Summary

The role of apoptosis in affinity maturation was investigated by determining the affinity of (4-hydroxy-3-nitrophenyl)acetyl (NP)-specific antibody-forming cells (AFCs) and serum antibody in transgenic mice that overexpress a suppressor of apoptosis, \(\text{bcl-x}_L\), in the B cell compartment. Although transgenic animals briefly expressed higher numbers of splenic AFCs after immunization, the \(\text{bcl-x}_L\) transgene did not increase the number or size of germinal centers (GCs), alter the levels of serum antibody, or change the frequency of NP-specific, long-lived AFCs. Nonetheless, the \(\text{bcl-x}_L\) transgene product, in addition to endogenous \(\text{Bcl-x}_L\), reduced apoptosis in GC B cells and resulted in the expansion of B lymphocytes bearing VDJ rearrangements that are usually rare in primary anti-NP responses. Long-lived AFCs bearing these noncanonical rearrangements were frequent in the bone marrow and secreted immunoglobulin G1 antibodies with low affinity for NP. The abundance of noncanonical cells lowered the average affinity of long-lived AFCs and serum antibody, demonstrating that \(\text{Bcl-x}_L\) and apoptosis influence clonal selection/maintenance for affinity maturation.

Key words: \(\text{Bcl-x}_L\) • apoptosis • affinity maturation • germinal center • clonal selection

A distinct property of humoral immune responses to T cell–dependent antigens is a progressive increase in antibody affinity known as affinity maturation (1, 2). Affinity maturation is achieved by two key events: the generation of antibody variants by V(D)J hypermutation and the subsequent selection of those variants that bind antigen strongly (3, 4). It is widely believed that the selective accumulation of high-affinity B cells is mediated by inter- and intraclonal competition for antigen retained on follicular dendritic cells (FDCs)† in germinal centers (GCs) (5–7). However, little is known about the cellular and molecular mechanisms underlying this selection.

GCs serve as a crucial site for antigen-driven V(D)J hypermutation (8, 9). Clonal selection and affinity maturation within this mutated population can be followed by a variety of methods (10, 11) to show that increased affinity is achieved by both preferential retention of higher-affinity B cells (positive selection) and loss of low-affinity B cells (negative selection). Although positive selection can only result from an active process, i.e., selective proliferation, negative selection can arise passively. For example, limiting amounts of antigen may be insufficient to activate B cells with low-affinity receptors (12) or to support their interaction with T lymphocytes (13). Such clones would be rapidly overgrown in the GC population by higher-affinity competitors. Nonetheless, negatively selected GC B cells are believed to die by apoptosis, because GCs are sites of considerable cell death, and in vitro, GC B cells undergo programmed cell death in the absence of activating stimuli (14). Furthermore, administration of large amounts of soluble antigen sharply elevates the number of apoptotic B cells in GCs, an experiment thought to mimic the negative selection of autoreactive mutants (15–17).

Several molecules that regulate apoptosis have been proposed to modulate negative selection during affinity maturation. Bcl-2, an inhibitor of apoptotic cell death, is selectively downregulated in GC B cells (18), and human GC B cells rapidly become apoptotic in ex vivo culture. How-
ever, stimulation of human GC B cells with antibody to membrane Ig (mIg) or CD40 extends the survival of cultured GC cells and upregulates Bcl-2 (14). Reciprocally, a positive regulator of apoptotic cell death, Fas (CD95), is highly expressed in GC B cells (18, 19), and GC B cells are susceptible to Fas-mediated apoptosis in vitro (20, 21). Despite these in vitro models, studies of genetically modified mice do not support major roles for Bcl-2 or Fas in affinity maturation. Neither the overexpression of Bcl-2 nor the lack of Fas has detectable effects on the affinity maturation of serum antibodies (19, 22). These findings raise the possibility that affinity maturation is achieved solely by positive selection, or that other apoptosis-regulatory molecules are involved in the negative selection process.

A homologue of bd-2, bd-x, also suppresses apoptosis through its Bcl-x product (23). Bcl-x is highly expressed in pre-B cells but is downregulated when B cells enter the mature pool (24, 25). While Bcl-2 plays a critical role in the survival of mature naive lymphocytes (26), Bcl-x is important for the survival of immature lymphocytes (27). Interestingly, cross-linking of mlg or CD40 on splenic B cells upregulates the expression of Bcl-x (25, 28). Human GC B cells are also known to reexpress Bcl-x, with expression confined to the centrocyte subset in which clonal selection is thought to occur (29, 30). These data and the many shared characteristics of immature and GC B cells (31) suggest that Bcl-x might control life-or-death decisions in the GC compartment.

To examine the roles of apoptosis and Bcl-xL in affinity maturation, we tracked the affinity of antibody-forming cells (AFCs) in the bone marrow (BM) and serum antibody of bd-xL transgenic mice and their congenic wild-type controls, during the clonally restricted antibody response to the (4-hydroxy-3-nitrophenyl)acetyl (NP) hapten (32). Our study revealed that overexpression of Bcl-xL did not change the magnitude of the GC response or the frequency of AFCs in the BM. However, apoptotic cell death in GCs was significantly reduced in bd-xL transgenic mice and led to the persistence of many B cells carrying VDJ rearrangements that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare in the later stages of the primary anti-NP response and generally encode lower-affinity mAbs that are normally rare.
Flow Cytometry. Single cell suspensions of splenocytes and BM cells were prepared as described (11). Cells were then washed in PBS (pH 7.4) containing 2% FCS and 0.08% sodium azide at 4°C for cytometric analysis, or washed with deficient RPMI 1640 (Irvine Scientific) containing 2% FCS for sorting. The enumeration of GC B cells and sorting of BM AFCs were carried out as described (11).

To collect GC B cells, splenocytes pooled from four mice were blocked with anti-FcγRI/RII and then stained with biotinylated anti-IgD, -MAC-1, -Gr-1, -Thy1.2, -CD4, -CD8, and -Ter119 antibodies for 30 min. After three washes, cells were incubated with streptavidin-conjugated microbeads (Miltenyi Biotec) for 15 min. Cells attached to microbeads were depleted by passage through a C57BL/6 J anti-Thy1.2 antibody and a final wash step. Recovered cells were stained with FITC-labeled anti-CD3, PE-conjugated anti-B220, TIC-color-conjugated streptavidin (Caltag Laboratories), and 7-amino-actinomycin D (7-AAD). Finally, GL-7 B220+ cells within the TIC-color 7-AAD+ fraction were sorted into biotin-deficient RPMI containing 2% FCS using a FACStarPlus (Becton Dickinson). GL-7 B220+ cells were sorted from the same pooled splenocytes without preenrichment by depletion with magnetic beads. To collect B220+ cells and CD3+ cells, splenocytes from naive bcl-xL transgenic and control mice were blocked and stained with FITC-labeled anti-CD3 and PE-conjugated anti-B220 antibody, and then single positive cells were sorted by the same procedure. Sorting routinely yielded populations >97% purity.

Western Blots. Cells were lysed in a buffer containing 137 mM NaCl, 1 mM MgCl2, 0.1 mM CaCl2, 20 mM Tris-HCl (pH 9.0), 1% NP-40, and 10% glycerol. After homogenization, cells were centrifuged and supernatants were recovered. The cell lysates or anti–Bcl-2 mAbs, then washed five times with TBS containing 0.1% Tween-20. After incubation with 1:20,000 diluted HRP-conjugated goat anti–mouse Ig antibodies (Amersham Pharmacia Biotech), the reaction was developed by enhanced chemiluminescence using the ECL kit (Amersham Pharmacia Biotech) and detected by exposure to X-ray film.

Results

bd-xL transgene Protects B Cells from Passive Apoptotic Death. Spleens of mice carrying the bd-xL transgene are ~50% larger and contain 30% more mononuclear cells than those of nontransgenic littermates. This increased cellularity is due to a near doubling in the number of mature IgM+ B220+ cells (Fig. 1 A). Flow cytometric analyses of splenic B cells from transgenic mice revealed that expression of IgM, IgD, CD19, CD21, CD22, CD23, and CD24 was identical to that of control littermates (data not shown). Despite the increased numbers of peripheral B lymphocytes, transgenic animals displayed normal levels of serum IgM (1,242 ± 351 vs. 1,295 ± 379 μg/ml) and IgG (1,341 ± 101 vs. 1,777 ± 379 μg/ml) as measured by specific ELISA. As expected (24), the thymic and peripheral T cell compartments of transgenic mice were normal in size and cellular composition (Fig. 1 A, and data not shown).

Initial assays were performed to assess the ability of transgene-bearing B cells to survive in culture medium containing little FCS. Purified splenic B cells from transgenic mice showed a significant survival advantage over control cells

Figure 1. B cells from bcl-xL transgenic mice are resistant to passive cell death and proliferate in vitro in response to activated helper T cell clones or recombinant CD40L. (A) The bcl-xL transgene expands the peripheral B cell compartment. Transgenic animals exhibit increased splenic cellularity that reflects a near doubling of naive IgM+ B lymphocytes. In contrast, thymic weight and cellularity are unchanged. Values represent mean ± SEM of 4x to nine bcl-xL transgenic mice or wild-type littermate controls. Splenic weight, cellularity, and B cell number are significantly (P < 0.01) greater in transgenic mice than in normal controls. (B) Splenic B cells were purified from control (filled symbols) or transgenic (open symbols) mice and cultured in medium containing 1% FCS for 96 h. Viable cells present in triplicate cultures were enumerated by trypan blue exclusion at the indicated times; each point represents the mean number (± SD) of viable B lymphocytes. (C) Purified control and transgenic B cells (1.5 × 106 cells/well) were cultured for 48 h in the presence of helper T cells activated by immobilized CD3-specific antibody (squares) or rCD40L (circles). [3H]Thymidine uptake by the cultured cells was then determined to estimate cellular proliferation. Stimulating T cells were diluted threefold from 3 × 104 cells/well, and medium enriched for rCD40L was serially diluted in threefold steps from 0.3%.
when cultured in medium containing 1% (Fig. 1 B) or 0.1% serum (not shown), indicating their strong resistance to the effects of serum starvation.

Despite their resistance to serum starvation, transgenic B cells displayed no evidence for increased proliferation in response to CD40 cross-linking or T cell help in vitro (Fig. 1 C). In addition, proliferative responses and antibody production in cultures containing LPS were the same for both transgenic and control splenocytes.

Expression Pattern of Endogenous and Transgenic Bcl-xL in Splenic Lymphocytes. The product of the bd-xL transgene carries a short epitope tag at its N terminus and migrates more slowly in SDS-PAGE gels than endogenous Bcl-xL, which runs as a doublet at ~31 and 32 kD. Fig. 2 A illustrates that transgenic Bcl-xL is expressed almost exclusively in the B220+ fraction of splenic lymphocytes. To define transgene expression in B cells participating in an immune response, C57BL/6 mice were immunized with NP-CG, and 12 d later splenic B220+ cells were sorted into GL-7- and GL-7+ fractions to identify follicular and GC B cells, respectively (31). The expression of endogenous Bcl-2 and of endogenous and transgenic Bcl-xL in these populations were then compared (Fig. 2 B).

Follicular B (GL-7+B220+) cells from wild-type mice are positive for Bcl-2 but express little Bcl-xL. Both proteins are abundant in the follicular population of mice carrying the bd-xL transgene. In contrast, GC B cells (GL-7+B220+) isolated from both wild-type and transgenic mice abundantly express Bcl-xL but little or no Bcl-2. This observation is consistent with studies of GCs in humans (18, 30). Thus, the reciprocal expression of Bcl-xL and Bcl-2 observed in pre-B cells holds for GC B cells (24, 25). Interestingly, although transgenic Bcl-xL is strongly expressed in follicular B cells, only modest amounts of tagged Bcl-xL could be demonstrated in GC B cells. Reverse transcription PCR studies confirm lower steady state levels of transgenic Bcl-xL message in the GL-7- B cell population (data not shown). This biased expression of transgenic Bcl-xL may represent distinct Eμ activity in each B cell compartment (the density of mlg on GC B cells is ~10% of that found on follicular B cells [29]) or downregulation of the transgene’s herpes TK promoter in activated cells (24).

GCs develop normally in bd-xL transgenic mice. To assess the effects of the bd-xL transgene on GC development, we compared the GC reaction of transgenic and control mice at day 12 after immunization with NP-CG. This antigen elicits a characteristic hapten-specific antibody that bears a λ1 L chain and an H chain encoded by a canonical VDJ gene rearrangement (32). We identified λ1+ GCs in spleen sections by labeling with PNA and anti-λ1 antibody (32) and determined the average number of λ1+ GCs per section from groups of transgenic and control mice (Fig. 3 A). Differences in the number or size (data not shown) of GCs were not observed between the groups, nor did the mean frequency of λ1+ GCs significantly differ between transgenic (35.4%) and wild-type mice (41.7%). When transgenic mice were immunized with carrier protein alone, the average frequency of λ1+ GCs was 7.6%. Thus, frequent λ1+ GCs in transgenic mice result from immunization with NP rather than altered λ1 L chain expression.

The frequencies of splenic GC B cells (GL-7+B220+ fraction) in transgenic and control mice were also determined by flow cytometry. Both groups supported equivalent and typical GC responses (Fig. 3 B): in transgenics, the frequency of GC B cells peaked at an average of 2.46% of splenocytes compared with 2.39% in controls at day 12 after immunization. Proliferative activity in the GC compartments of both transgensics and controls was also equivalent; 10 d after immunization, 21 vs. 24% of PNA+ GC cells were labeled by a 2-h pulse of BrdU (not shown).

Transgenic Bcl-xL Increases Splenic AFC Numbers but not Their Longevity or Serum Antibody Titers. T cell–dependent antigens induce two distinct populations of AFC, a short-lived splenic population that generates the earliest primary antibody and a long-lived set in the BM that maintains the serum response (10, 11). Frequencies of NP–specific, IgG1, AFCs in the spleen and BM of transgenic and control mice were determined by ELISPOT assay 12, 35, and 69 d after immunization (Fig. 3 C). The kinetics of AFC production were virtually identical in both groups of mice, but splenic AFCs were threefold more abundant in transgenic mice than in controls. This increase may reflect the approximately twofold increase in the number of B cells in the spleens of transgenic mice (Fig. 1 A). Despite their greater

Figure 2. Expression of endogenous and transgenic Bcl-xL in splenocytes. Expression patterns of Bcl-x1 and Bcl-2 were determined by Western blotting of splenocytes from bd-xL transgenic mice or wild-type littermate controls. (A) Unselected (total splenocytes [Total spl], lane 1), lymphoid gate (lane 2), and sorted BL220+CD3- (lane 3; B220-CD3-, lane 4) splenocytes were recovered from naive transgenic mice. Most, if not all, transgenic Bcl-xL protein detected in these populations is confined to splenic B lymphocytes. (B) Spleen cells from four immunized transgenic or wild-type mice were pooled at day 12 after immunization. 10 μg of cell lysate protein was immunoblotted using anti-Bcl-x (upper panel) or anti-Bcl-2 (lower panel) mAbs. Molecular masses: transgenic Bcl-xL, 33 kD; endogenous Bcl-xL, 31, 32 kD; Bcl-2, 26 kD. Transgenic Bcl-xL protein is abundant in follicular (GL-7+B220+) B cells, but only modest amounts are present in GC B lymphocytes (GL-7+B220+). Endogenous Bcl-xL is expressed at low levels in follicular B cells but is upregulated in the GC. In contrast, Bcl-2 is present in quantity in the follicular population but undetectable in GC B cells.

Downloaded from on June 27, 2017
numbers, splenic AFCs in transgenic mice were lost at the same rate as in control animals. This rapid decline contrasts with bcl-2 transgenic mice, which support higher numbers and longer-lived splenic AFCs (22). Frequencies and kinetics of specific BM AFCs were indistinguishable between transgenic and control mice (Fig. 3 C).

The expanded splenic AFC pool in transgenic mice resulted in a minor increase in serum antibody titers on day 12, but later levels of antibody did not differ significantly between transgenic and control mice. In both groups, antibody concentrations were at maximal levels on day 12 and then slowly declined to about one third of this peak by day 69 (Fig. 3 D). Thus, overexpression of Bcl-xL modestly expands recruitment into the splenic AFC pool but does not change cellular recruitment into GCs, entry into the BM AFC pool, or maintenance of long-lasting serum antibody.

**bcl-xL Transgenic Mice Have Fewer Apoptotic Cells in GCs.**

GCs contain more apoptotic lymphocytes as determined by TUNEL (17). These TUNEL+ cells are thought to represent lymphocytes that have been negatively selected during the GC response. We performed TUNEL assays on spleen sections from transgenic and control mice to determine if the small addition of transgenic Bcl-xL expressed in GC B cells was sufficient to reduce programmed cell death. TUNEL+ cells in GCs from both groups were counted by microscopic examination, and the frequency of TUNEL+ cells per unit area was calculated. These frequencies were subdivided into 12 categories, and the distribution histogram for each category was plotted (Fig. 4). GCs from bcl-xL transgenic mice contained fewer TUNEL+ cells per unit area (P < 0.01) than those from control mice (Fig. 4). The most common apoptotic index in wild-type animals was 2.0–2.5 TUNEL+ cells/unit area but only 1.0–1.5 in the bcl-xL transgenics. Perhaps more significantly, >20% of GCs in control mice contained >3 TUNEL+ cells/unit area, whereas only 5% of GCs in bcl-xL transgenic animals held 3.0–4.0 apoptotic cells/unit area with no GCs in the 4.5–6.0 categories. Thus, a modest addition of Bcl-xL in transgene-bearing GC B cells leads to a readily detectable decrease of TUNEL+ cells.

**GC B Cells Using Noncanonical VDJ Rearrangements Are More Frequent in bcl-xL Transgenic Mice.**

The expanded splenic AFC pool in transgenic mice resulted in a minor increase in serum antibody titers on day 12, but later levels of antibody did not differ significantly between transgenic and control mice. Frequencies and kinetics of specific BM AFCs were indistinguishable between transgenic and control mice (Fig. 3 C).

Relaxed Affinity Maturation in bcl-x<sub>L</sub> Transgenic Mice

Zonation with NP conjugates stimulates a broad population of splenic B cells that bear the λ1 L chain and H chain genes made from the V186.2 and V3 subgroups of the J558 V<sub>H</sub> gene family (34). Until day 6–7 of the primary response, many GC B cells express VH gene segments that closely resemble the canonical V186.2 element but encode lower-affinity NP-binding antibodies (12, 34, 36, 37; and Shimoda, M., and G. Kelsoe, unpublished data). By day 10, the majority of B cells bearing these noncanonical VH gene rearrangements are replaced by higher-affinity cells bearing V186.2/DFL16.1 rearrangements and a tyrosine-rich junctional motif, YYGS (12, 34). Thus, after day 10 the efficiency of affinity-based competition is estimated by the ratio of GC B cells bearing V186.2 versus related V<sub>H</sub> genes.

Cells were microdissected from a total of 27 λ1 L GCs from 4 transgenic and 4 control mice 12 d after immunization with NP-CG. VDJ rearrangements from both groups of mice were amplified by PCR and cloned into bacteria, and 600 bacterial colonies were then subjected to hybridization using V186.2-specific and subgroup-specific primers. About 80% (64/81) of VDJ fragments recovered from control mice selectively hybridized to the V186.2 V<sub>H</sub> gene segment, consistent with previous studies (12, 34), whereas fewer than half (261/554) of the VDJ fragments amplified from bcl-x<sub>L</sub> transgenic mice exhibited preference for V186.2.

These hybridization data were confirmed by sequencing VDJ inserts from representative bacterial colonies (Table I). From normal C57BL/6 control mice, 79% (11/14) of sequenced VDJ rearrangements contained the V186.2 gene segment, confirming our hybridization analysis and prior sequence studies (33). In contrast, only 47% (17/36) of sequenced VDJ fragments from bcl-x<sub>L</sub> transgenics carried the canonical V186.2 element (Table I). Noncanonical rearrangements from both control and transgenic mice contained other V<sub>H</sub> genes from the V186.2 and V3 subfamilies (35) commonly recovered in early primary anti-NP responses (12, 34).

The use of noncanonical VDJ rearrangements by immunized transgenic mice was not due to altered usage of VH gene segments in naive λ1 L cells. We recovered splenic λ1 L B<sup>220</sup><sup>+</sup> cells from unimmunized, transgenic, and wild-type mice by fluorescence-activated cell sorting, amplified their VDJ rearrangements with the PCR primers used to study GC populations, and determined the ratios of VDJ rearrangements containing V186.2 versus related V<sub>H</sub> genes. There was no significant difference in the percentage of V186.2 genes used by naive Bcl-x<sub>L</sub> transgenic mice (14%; 12/88) and naive controls (16%; 12/74). These observations suggest that even slight overexpression of Bcl-x<sub>L</sub> in GC B cells leads to lower numbers of TUNEL<sup>+</sup> GC cells and the persistence of clones bearing noncanonical VDJ rearrangements that commonly encode low-affinity antibodies present early in the primary response to NP.

The abundance of noncanonical VDJ rearrangements was not associated with impaired positive selection. Patterns of mutation in VDJ rearrangements containing the

canonical V186.2 gene segment were similar in transgenic and control mice, with no significant difference (P > 0.05) in the ratios of replacement versus silent mutations (R/S ratios) in CDRs (Table I). Other characteristics indicative of high-affinity, NP-specific B cells, e.g., the fraction of rearrangements containing DFL16.1 and the YGYSG CDR3 motif, were also similar in both groups. Thus, cellular recruitment, V(D)J hypermutation, and positive selection in GCs are unaffected by the bcl-x<sub>L</sub> transgene.

Transgenic Bcl-x<sub>L</sub> Leads to Impaired Affinity Maturation in the BM AFC Compartment and Serum Antibody. Serum antibody is maintained by long-lived BM AFCs that depend on the GC differentiation pathway (10, 11, 38, 39). Affinity maturation of serum antibody and the BM AFC compartment can be monitored by differential binding to ELISA or ELISPOT substrates with sparse (NP<sub>2</sub>) or dense (NP<sub>23</sub>) hapten coatings (10, 11). High-affinity antibody from serum and AFCs binds equally well to both hapten densities, whereas low-affinity binding is evident only on the NP<sub>23</sub> substrate.

The high-affinity compartment of BM AFCs in wild-type mice rapidly increased between days 12 (30.3%) and 35 (75.6%) of the response, with a more gradual increase up to day 69 (88.4%) (Fig. 5 A). This kinetic is typical of normal responses (11). At day 12, high-affinity AFCs were as common in the BM of transgenic mice (34.3%) as in controls. However, this population expanded more slowly in animals with the bcl-x<sub>L</sub> transgene, reaching only 57.5 and 60.6% by days 35 and 69, respectively (Fig. 5 A). Remarkably, at day 69 of the response three transgenic mice had a population (53%) of mice with the noncanonical VDJ rearrangements present in day 12 GCs (47%; Table I) was maintained in the day 69 BM AFC compartment. Interclonal competition in both BM AFCs and the serum antibody.

Impaired Affinity Maturation in Transgenic Mice Is Reflected in the Somatic Genetics of the BM AFCs. To determine the cause of decreased affinity in the BM AFCs of transgenic mice, we recovered the λ<sup>+</sup> BM AFC populations from immunized wild-type (n = 5) and transgenic (n = 5) mice by cell sorting (11). Typically, at day 69 after immunization >50% of sorted cells from both groups of mice secreted IgG<sub>1</sub> antibody specific for NP. Enriched BM AFC populations were subjected to a reverse transcription PCR that preferentially amplifies cDNA representing rearrangements of the V186.2 and V3 subfamilies of VH gene segments. Amplified VDJ rearrangements were cloned and sequenced to identify the VH, D, and J gene segments used and any mutations present. Table II summarizes this work and shows that only half (11/21) of the VDJ sequences recovered from bcl-x<sub>L</sub> transgenic mice used the V186.2 gene segment. In contrast, nearly all (16/17) VDJ rearrangements from wild-type mice contained the V186.2 gene segment. Thus, the high frequency of B cells bearing noncanonical VDJ rearrangements present in day 12 GCs (47%; Table I) was maintained in the day 69 BM AFC population (53%) of mice with the bcl-x<sub>L</sub> transgene. The reduced average affinity of BM AFCs in bcl-x<sub>L</sub> transgenic mice results from the retention of B cells bearing noncanonical VDJ rearrangements. Interclonal competition in both BM AFCs and serum antibody.

After day 35, the population of high-affinity BM AFCs grew twice as fast in wild-type mice as in transgenics (Fig. 5) even though both groups supported equivalent numbers of NP-specific, IgG<sub>1</sub> AFCs (Fig. 3). Administration of anti-CD154 antibody to abrogate the GC reaction and reduce the genetic diversity present in the BM AFC compartment (11, 40) enhanced this difference. Control mice that received the CD154-specific antibody, MR1, on days 6, 8, and 10 after immunization had a high-affinity BM AFC compartment of 15.1% at day 22 of the response that grew to 55.8% by day 69 (data not shown). Immunized transgenic mice that received MR1 antibody began with a comparable high-affinity AFC compartment, 12.0% at day 22, but this population grew to only 22.0% by day 69. Thus, overexpression of Bcl-x<sub>L</sub> also retards affinity maturation outside the GC microenvironment.

### Discussion

In this report, we have demonstrated that a bd-x<sub>L</sub> transgene reduces apoptosis in the GC reaction and impairs affinity maturation by sparing cells normally lost from the primary response. This transgene also enhances the survival of peripheral B cells in response to serum starvation in vitro and rescues developing B lymphocytes with aberrant VDJ rearrangements. These effects represent supplementation of endogenous Bcl-x<sub>L</sub> activity; although Bcl-x<sub>L</sub> is abundant in the GL-7<sup>+</sup>B220<sup>+</sup>GC cells of wild-type mice, Bcl-2 is not (Fig. 2 B). Similar observations have been reported for human GC cells where Bcl-x<sub>L</sub> rather than Bcl-2 mediates the CD40-dependent survival of centrocytes ex vivo (30).

This result contrasts with that of Bcl-2 overexpression, which does not interfere with affinity maturation (22) but permits the survival of mature autoreactive B cells in the periphery (41). The bd-x and bd-2 transgenes also act differently during negative selection in immature B cells, as transgenic Bcl-x<sub>L</sub> has the ability to block negative selection and promote developmental maturation, whereas autoreactive cells transgenic for bd-2 remain arrested in development (42, 43). Given the similar reciprocal expression of bd-2 and bd-x in GC B cells and pre-B cells, bd-x may have a distinct role in regulating the survival of B cells undergoing selection via mlg or the pre-B cell antigen receptor (BCR) (24, 30). Bcl-x<sub>L</sub> becomes abundant in B cells after cross-linking mlg or CD40 (25, 28), and the fate of GC B cells is controlled by these same signals (40). We speculate that the degree or quality of mlg signaling in low-affinity B cells does not induce Bcl-x<sub>L</sub> expression as effectively as in high-affinity cells, and that this deficit leads to apoptosis. That even a slight addition of transgenic Bcl-x<sub>L</sub> to the higher levels of the endogenous protein in GC B cells leads to significant effects on cell death and affinity maturation indicates that GC B cells are quite sensitive to small changes in levels of this death antagonist. The fate of lower-affinity GC B cells appears to be determined by a regulatory threshold of Bcl-x<sub>L</sub>.

Rrelaxed negative selection and the retention of low-affinity B cells in transgenic mice did not alter the duration...
or magnitude of the GC response in bcl-x<sub>L</sub> transgenic mice (Fig. 3). At 35 d after immunization, the splenic GC reaction had ended both in transgenic (0.33% GL-7<sup>B</sup>B220<sup>+</sup> spleen cells) and control (0.37%) animals. This is the earliest time after immunization that the numbers of splenic GL-7<sup>B</sup>B220<sup>+</sup> cells return to preimmune levels in normal mice (11). Thus, the GC response appears to be regulated by factors beyond affinity-driven competition and selective apoptosis. The rise and fall of GCs depend on the presence of antigen, sustained cell–cell interactions, and cues for cellular localisation (40, 44–47). It is not surprising that this important immunological response is controlled by finer means than that afforded by Darwinian competition alone.

Nie et al. (37) have reported that immunization of C57BL/6 mice with complexes of antibody and antigen elicits lower-affinity serum antibody and a genetically diverse GC reaction similar to that we observe in bcl-x<sub>L</sub> transgenic mice. These authors hypothesize that immune complexes decorated with C3d efficiently recruit the CD21/CD19/CD81 coreceptor to antigen-binding BCRs to reduce the threshold of B cell activation. Lowered activation thresholds would result in reduced levels of affinity-driven selection. Although Nie and colleagues describe a phenotype similar to that of bcl-x<sub>L</sub> transgenic mice, we think it is unlikely that Bcl-x<sub>L</sub> reduces selection intensity by enhancing BCR signals. Background levels of IgM and IgG are similar in the serum of transgenic and control mice, and both contain only trace amounts of N P-binding IgG before immunization. Thus, immune complexes are no more likely to form in bcl-x<sub>L</sub> transgenics than in wild-type controls after primary immunization. Our data support the notion that enhanced BCR signals, perhaps mediated by coreceptor recruitment, result in reduced apoptosis immunization with immune complexes may facilitate Bcl-x<sub>L</sub> expression in responding B lymphocytes.

A possible mechanism for continued selection by apoptosis outside of GCs is competition among memory B cells for restimulation (48, 49). However, memory B cells are thought to regain Bcl-2 expression, and it would be surprising if their survival depended also on Bcl-x<sub>L</sub> (18). Alternatively, selective competition among BM AFCs for antigen might drive sustained affinity maturation. BM AFCs express low levels of mlg (11) and could interact with antigen deposits in a Bcl-x<sub>L</sub>-dependent fashion. Indeed, plasma cytomas express Bcl-x<sub>L</sub> (50), and human plasma cells exhibit high levels of Bcl-x<sub>L</sub> but low levels of Bcl-2 (51), although it is unclear if these cells represent long- or short-lived AFCs. It will be important to learn how BM AFCs integrate the usually antagonistic processes of differentiation to antibody secretion and cellular longevity so as to maintain protective levels of serum antibody over long time periods.

Our data provide strong evidence of a continuing role for antigen in the maintenance of the long-lived AFC pool. However, Manz et al. (38) have reported that the transfer of BM AFCs into unimmunized recipients reconstitutes long-term serum antibody and conclude that antigen is unnecessary for the survival of these cells. Such experiments are complicated by the possibility of coincidental transfer of residual antigen (6, 7, 48), but we cannot exclude the possibility that post-GC selection acts on precursors of the long-lived AFC pool. In this case, the characteristic somatic genetic changes observed in BM AFCs (11; Tables I and II) would first occur in the precursor population. Such selection would be antigen dependent and affinity driven. Recent work on the longevity and affinity of BM AFCs and serum antibody (our unpublished studies) support the importance of antigen retention and/or BCR signaling in shaping the long-lived AFC population. What remains unchallenged is that affinity maturation of serum antibody continues for months after primary immunization (1, 2, 11; Fig. 5). Although this progressive increase in affinity could be programmed in the early phase of the response, we suggest that in some way antigen continues to exert selection on the responding B cells.

We gratefully acknowledge the assistance of M. Gendelman, and the additional flow cytometric and BrdU-labeling data provided by Dr. B. Zheng. We thank T. F. Tedder, S. Foster, and M. Davila for help with the manuscript.
