IL-1α (IL-1F1) and IL-1β (IL-1F2) are related cytokines involved in inflammation in a variety of tissues and diseases (1, 2). Both are ligands for a heterodimeric receptor composed of the type I IL-1R (IL-1R) and IL-1R accessory protein (AcP; IL-1RAcP) (3). Either IL-1α or β can bind to IL-1R, but this alone does not activate signal transduction. Binding of the ligands to IL-1R results in recruitment of AcP to the complex, resulting in juxtaposition of intracellular IL-1R and AcP TIR (Toll/IL-1R) domains, and activation of signal transduction (2). Another related ligand, IL-1R antagonist (IL-1ra and IL-1F3), competes with IL-1α and -1β for binding to IL-1R. The IL-1R–IL-1ra complex cannot recruit AcP, and is incapable of signaling (4). Type II IL-1R and a soluble form of AcP are involved in additional layers of IL-1 regulation (5, 6).

IL-18 (IL-1F4) is another IL-1 ligand family member involved in inflammation (7, 8). IL-18R and -18RAcPL comprise the functional IL-18R (9). A natural antagonist of this system, IL-18–binding protein (IL-18bp), is not an IL-1 family member and acts by sequestering IL-18, preventing it from binding to its receptor (10). Therefore, IL-18bp and -1ra act to antagonize their respective cytokines by distinct mechanisms.

Several IL-1 ligand and receptor family members have been implicated in cutaneous inflammation. Transgenic mice expressing IL-1A from the keratin 14 (K14) promoter develop focal inflammatory skin lesions, hair loss, and scaling. At the histological level, the transgenic mice have hyperkeratosis and dermal inflammation mainly...
composed of macrophages, but no alteration in epidermal thickness (11). Transgenic mice expressing *IL18* from the keratin 5 promoter exhibit many features of atopic dermatitis, including acanthosis; an infiltrate composed of eosinophils, neutrophils, and mast cells; an increase in serum IgE levels; and an increase in B cells in the draining lymph node (12). In a BALB/c genetic background, *IL1RN*-deficient mice have histological features in common with psoriasis (13). Mice deficient in *IL1R1*, *IL1RAP*, *IL18R1*, and *IL18RAP* have no overt skin abnormalities (14–18).

Genes encoding several IL-1–related ligands (from *IL1F5* to *IL1F10*) have been discovered and map to human chromosome 2q, the same locus as *IL1A*, -1B, and -1RN (1, 19–25). These IL-1F ligands lack signal sequences, and only IL-1F7 contains a proregion. Phylogenetic analysis indicates that *IL1F5* and *IL1F10* are most closely related to *IL1RN* (24, 25). *IL1F6*, -1F8, and -1F9 comprise a separate triplet branch of the phylogenetic tree.

There are now 10 known members of the IL-1R family (2). IL-1R rp2 (RP2) was originally identified as an IL-1R family member expressed in the brain (26). IL-1F9 was demonstrated to activate signal transduction in an RP2-dependent manner (27). In addition, IL-1F9 activation of RP2 was antagonized by IL-1F5. These results have been extended by the demonstration that IL-1F6 and -1F8, in addition to IL-1F9, activate signal transduction pathways and require both RP2 and AcP (28). Quantitative RT-PCR analysis indicates that *IL1F6*, -1F8, and -1F9 are expressed in a restricted manner, primarily in the skin and in other epithelial tissues, whereas *IL1RL2* and *IL1RAP* are more widely expressed (unpublished data) (28).

We report that transgenic expression of *IL1F6* in basal keratinocyte cells results in cutaneous alterations in both the

Figure 1. K14/IL1F6 transgenic pups have skin abnormalities.

(A) K14/IL1F6 transgenic pups have flaky skin, ringtail, and are runted. The gross phenotype of a K14/IL1F6 transgenic (Tg+) pup and a nontransgenic (Tg−) cagemate at 7 d of age is shown. (B) Skin from K14/IL1F6 transgenic pups is hyperkeratotic, acanthotic (increased epidermal thickness), and contains a dermal inflammatory cell infiltrate. HE staining of skin from a K14/IL1F6 Tg+ and Tg− pup at 7 d of age is shown. (C) Skin from K14/IL1F6 transgenic pups has increased expression of keratin 6 and ICAM-1, and an increased number of BM8+ macrophages, CD205+ Langerhans or dermal dendritic cells, and CD3+ T lymphocytes relative to skin from nontransgenic littermate control pups. CD205+ staining most likely represents Langerhans cells, as the majority of the signal is epidermal. IHC staining of skin from K14/IL1F6 Tg+ and Tg− pups at 7 d of age with specific antibodies is shown. Bar, 100 μm. (D) Chemokines and cytokine protein levels are elevated in the skin of K14/IL1F6 transgenic pups compared with nontransgenic littermate pups. Skin was isolated from 7-d-old K14/IL1F6 Tg+ and Tg− pups, protein extracts were prepared, normalized to total protein, and analyzed by Rules Based Medicine MAP profiling. MIP2, CXCL8 (IL-8); GCP2, CXCL6; MCP-3, CCL7. (E) Epidermal thickness is increased in the skin of K14/IL1F6 transgenic pups at P5, 7, and 10 compared with nontransgenic cagemate control pups. Skin was isolated from K14/IL1F6 Tg+ and Tg− pups, stained with HE, and epidermal thickness was determined by histomorphometric analysis. Error bars in C and D represent the mean ± the SD. *, P < 0.05; **, P < 0.01; ***, P < 0.001.
Expression of IL1F6 in skin results in cutaneous inflammation

Importantly, we demonstrate that the severity of the skin abnormalities is increased in IL1F5–deficient mice, providing genetic evidence that IL-1F5 possesses antagonistic activity in vivo. We also demonstrate that IL1RL2, IL1F5, and IL1F6 expression is increased in human psoriatic skin, thus suggesting a possible connection between the mouse skin phenotype and human pathophysiology.

RESULTS

Expression of IL1F6 in skin results in cutaneous inflammation

The human K14 promoter was used to express mouse IL1F6 in basal keratinocytes in transgenic mice. Nine founders were obtained, one of which had severe skin abnormalities and was killed. This mouse had the highest IL1F6 expression in skin of the founders. The next four highest expressers were developed into lines, all of which had a similar gross phenotype. The studies reported in this work were performed on a line with at least 70-fold higher mRNA levels in skin relative to the endogenous IL1F6 mRNA level (unpublished data). K14/IL1F6 pups were small, had flaky skin, and developed ringtail (Fig. 1 A). The skin phenotype was first observable at postnatal day (P) 5, was most severe at P7, and was overtly resolved by P21. However, recurrence of skin lesions, predominantly on the face, snout, and ears, developed in K14/IL1F6 mice at 6 mo of age.

Histological analysis on transgenic pups at P7 demonstrated acanthosis, hyperkeratosis, and a mixed inflammatory cell infiltrate in the dermis composed mainly of neutrophils, macrophages, and lymphocytes (Fig. 1 B). Histological changes in keratinocytes and immune cells were analyzed by immunohistochemistry (IHC). Increased immunoreactivity was observed in markers for keratinocyte hyperproliferation (keratin 6), macrophages (BM8), epidermal Langerhans and dermal dendritic cells (CD205), inflammation (intercellular adhesion molecule 1 [ICAM-1]), and T lymphocytes (CD3; Fig. 1 C). Levels of a variety of cytokines and chemokines in skin protein extracts were compared in 1 wk-old K14/IL1F6 pups and their nontransgenic littermates. Elevated levels of GM-CSF, MIP-2, GCP-2, and MCP-3 were observed in the transgenic skin relative to the nontransgenic control skin (Fig. 1 D).

To determine how the skin phenotype develops, we compared skin from K14/IL1F6 pups to their nontransgenic littermates at 1, 3, 5, 7, 10, 14, and 21 d after birth by histopathological analysis. During this time period, the mouse epidermis normally decreases in epidermal thickness. The maximal increase in epidermal thickness in K14/IL1F6 skin relative to nontransgenic skin was observed at P5 (Fig. 1 E). In contrast, the presence of a mixed dermal inflammatory infiltrate reached its peak at P7 (unpublished data). Resolution of the histopathological skin abnormalities began between P7 and 21, and progressed to normal skin by P21.

Resolution of the K14/IL1F6 skin phenotype

We considered several possible hypotheses to explain the resolution of the K14/IL1F6 skin phenotype that occurs between P7 and 21; silencing of the IL1F6 transgenic expression, decreased expression of the required RP2 and/or AcP receptor subunits (see Fig. 3), and increased expression of the IL-1F5 antagonist (see Fig. 4). Quantitative RT-PCR analysis was performed on IL1F6, IL1RL2, IL1RAP, and IL1F5 in the skin from transgenic and nontransgenic pups at P1, 3, 5, 7, 10, 14, and 21. IL1F6 mRNA is expressed at higher levels in transgenic pup skin than in the nontransgenic pup skin at all time points (Fig. 2 A). However, transgenic IL1F6 expression decreases over the 21-d time course. Expression levels of IL1F5, -1F8, and -1F9 are increased in the K14/IL1F6 transgenic skin relative to the nontransgenic skin, and decreased from P1 to P21 in parallel with IL1F6 transgene expression (Fig. 2 A). IL1RL2 mRNA levels are slightly higher in transgenic skin than in nontransgenic skin at P1 and 3, but not at later time points (Fig. 2 B). IL1RAP mRNA levels are not altered at any time point by the presence of the transgene (Fig. 2 B). Expression of IL23A, CSF2, TNF, IL1A, CCL2, KRT14, CXCL2, HBEGF, and AREG mRNA was increased at specific time points in the transgenic skin, relative to the nontransgenic control skin (Fig. 2 C). Therefore, decreased expression of the IL1F6 transgene, IL1F8, IL1F9, IL1RL2, and inflammatory cytokines and chemokines is observed over the first 3 wk of age.

To further characterize the decreased expression of the K14/IL1F6 transgene over time, IHC was performed on IL-1F6 and K14. The following three time points were selected for analyses: P1 (initiation of transgene–dependent expression changes), P5 (peak of increased epidermal thickness induced by transgene expression), and P10 (after resolution of the skin phenotype has begun). Expression of IL-1F6 was observed throughout the epidermis at P1 and P5 in the transgenic skin, with the highest levels observed in the superficial epidermis (Fig. 2 D). Expression of IL-1F6 in nontransgenic pup skin was only in the superficial layer at P1 and P5. In contrast, IL-1F6 expression in transgenic skin at P10 was only observed in the superficial epidermis, and it was similar in intensity to the endogenous, nontransgenic IL-1F6 level. To investigate expression of a skin marker at these same time points, we chose K14, as its promoter was used to drive IL-1F6 expression in the transgenic mice. K14 protein is found throughout the epidermis at P1 and 5 in transgenic skin, although a predominance of basal layer expression was observed at P5 (Fig. 2 E). However, K14 protein was only observed in the basal layer in the transgenic skin at P10, which is its normal localization as shown in the nontransgenic skin (Fig. 2 E). Therefore, it appears that IL1F6 transgene expression is silenced in parallel with the phenotypic resolution.

Receptor requirement for K14/IL1F6 skin phenotype

RP2 and AcP were shown to be required for activation of signal transduction in vitro by IL-1F6 (28). To determine whether these receptor subunits were required for the skin alterations in K14/IL1F6 pups, transgenic mice were crossed...
Figure 2. Quantitative RT-PCR and IHC analyses demonstrate reduced expression of IL-1F6 as the skin phenotype resolves. (A) Expression of IL1F5, -1F6, -1F8, and -1F9 in the skin decreases over the P1–21 time course. (B) Expression of IL1RL2 is elevated in transgenic skin relative to control skin at P1 and 3. Expression of IL1RL2 at P5–21, and expression of IL1RAP from P1–21 is not different in transgenic and nontransgenic skin. (C) Expression of IL23A, CSF2, TNF, IL1A, CCL2, KRT14, CXCL2, TGA2, HBEGF, and AREG is given in both transgenic and nontransgenic skin from P1 to 21. Total skin RNA was isolated from K14/IL1F6 transgenic and nontransgenic pups (n = 3) and was analyzed by quantitative RT-PCR. Expression of specific genes is relative to
into IL1RL2- or IL1RAP-deficient backgrounds. Mice deficient in IL1RL2 were generated as described in the Materials and methods. Mice lacking IL1RL2 were born at the predicted Mendelian ratios from heterozygous intercrosses and displayed no overt phenotypes on C57BL/6; 129 hybrid, C57BL/6, or FVB genetic backgrounds. Mice deficient in IL1RL2 or IL1RAP have normal skin in an unchallenged context. Transgenic pups carrying the K14/IL1F6 transgene and lacking the receptor subunit (−/−) were compared with littermates that were transgenic and were heterozygous (+/−) or wild-type (+/+ ) for the receptor subunit. Expected Mendelian ratios were observed for all crosses. Pups were scored by their gross phenotype and by histopathological analyses at P7. Nontransgenic pups had normal skin, whereas transgenic pups that were IL1RL2+/−, IL1RAP+/−, IL1RL2+/−, or IL1RAP+/− had a skin phenotype. However, transgenic pups lacking IL1RL2 or IL1RAP did not exhibit a phenotype (Fig. 3, A and B). Therefore, IL1RL2 and IL1RAP are required for the K14/IL1F6 skin phenotype.

To provide further support for the essential role of RP2 in mediating IL-1F6 activity, intraperitoneal injections of a neutralizing monoclonal antibody against mouse RP2 (M616) and an isotype-matched control antibody in K14/IL1F6 newborn pups were performed. Half of each litter was injected with 50 μg M616 on P1, 3, and 5, whereas the rest of the litter was marked and injected with 50 μg control antibody. Pups were killed on P7, and were subjected to genotyping and histological analyses. The skin phenotype was blocked by M616 administration, but not by treatment with a control antibody, confirming the RP2 requirement (Fig. 3 C).

The K14/IL1F6 transgene was crossed into an IL1R1-deficient background to determine if this receptor is required for the skin phenotype. IL1R1-deficient mice have no skin abnormalities in an unchallenged context. Expected Mendelian ratios were observed. K14/IL1F6 transgenic pups lacking IL1R1 exhibit a skin phenotype similar in severity to K14/IL1F6 pups containing IL1R1 (Fig. 3 D). Therefore, IL1R1 is not required for the K14/IL1F6 skin phenotype.

**Immune requirements for the K14/IL1F6 skin phenotype**

TNF-α is an important cytokine in skin inflammation, and its blockade is an effective treatment for psoriasis (29). TNF-α mRNA is elevated in the skin of K14/IL1F6 pups from P1-P14 (Fig. 2 C). To determine if the K14/IL1F6 transgenic skin phenotype is dependent on TNF-α, K14/IL1F6 pups were treated with TN3-19.12 (30), a neutralizing antibody against mouse TNF-α. Transgenic pups treated with anti-TNF-α have a statistically significant decrease in epidermal thickness (Fig. 4 A) and a much more dramatic reduction in the amount of dermal immune infiltrate (Fig. 4 B) compared with pups treated with a control antibody. Additionally, K14/IL1F6, TNFRSF1A−/− (p55) pups had a similar decrease in epidermal thickness and dermal infiltrate compared with K14/IL1F6, TNFRSF1A−/− (p55) pups (unpublished data). Therefore, TNF-α and TNFRSF1A are not required for the K14/IL1F6 skin phenotype, but they do modulate the severity of the skin lesion, especially the amount of dermal inflammation.

Expression of chemokines involved in neutrophil mobilization is elevated in the skin of K14/IL1F6 pups (Fig. 1 D and Fig. 2 C), leading to the recruitment of neutrophils to the dermis (Fig. 1 B). To understand the functional role of neutrophils in the transgenic skin, pups were treated with the neutrophil-depleting antibody anti-Gr1 (31) or with an isotype-matched control antibody. Most of the neutrophils in the skin were depleted with anti-Gr1 treatment relative to those treated with the control antibody (Fig. 4 D). However, some neutrophils were still detected in the skin. Decreased neutrophil numbers with anti-Gr1 treatment resulted in a lower inflammation severity ranking (Fig. 4 C), but there was little effect on the epidermal thickness (unpublished data). Because of incomplete depletion, we cannot prove that neutrophils are dispensable for the generation of the IL-1F6-induced skin abnormalities. However, we can conclude that elimination of the majority of skin neutrophils primarily has its effect on the dermal infiltrate.

There is an increase in CD3+ T lymphocytes in the skin of K14/IL-1F6 pups compared with the skin of nontransgenic littermates (Fig. 1 C). To determine the role that lymphocytes play in the generation of the skin phenotype, the K14/IL1F6 transgene was crossed onto a RAG2-deficient background (32). IHC with anti-CD3 demonstrated that T lymphocytes were indeed absent in the skin of K14/IL1F6, RAG2−/− pups (Fig. 4 E). No differences were observed in the skin at the gross level, and only a slightly decreased severity between K14/IL1F6, RAG2−/− pups and K14/IL1F6, RAG2+/− pups was noted histologically. In addition, the expression of the inflammatory marker ICAM-1 was not altered (Fig. 4 E). Therefore, mature lymphocytes are also not required for the observed skin abnormalities in the K14/IL1F6 transgenic pups.

**Exacerbation of the K14/IL1F6 skin phenotype in IL1F5+/− and −1F5+/− mice**

IL-1F5 antagonizes the RP2-dependent signal transduction in vitro in response to IL-1F9 (27). Because IL-1F6 has similar activity to IL-1F9 in vitro (28), we tested whether IL-1F5 can also block the effect of this ligand. IL-1F5 antagonized IL-1F6 activity in a variety of in vitro assays (unpublished data). Substantial inhibition was observed at an equimolar IL-1F5/−1F6 ratio, which is consistent with published results (27).

β-actin, *, P < 0.05; **, P < 0.01; ***, P < 0.001. Error bars in A–C represent the mean ± the SD. (D) Protein expression of IL-1F6 in K14/IL1F6 transgenic pup skin is elevated at P1 and P5 relative to nontransgenic control skin, but is decreased to the endogenous level by P10. (E) K14 protein was detected throughout the epidermis in transgenic pups at P1 and 5, and is observed only in the basal layer at P10. Skin samples were fixed in neutral buffered formalin, sectioned, analyzed by IHC using a monoclonal antibody against mouse IL-1F6 or a polyclonal antibody against K14. Bar, 100 μm.
To study whether IL-1F5 can affect the severity of the K14/IL1F6 skin phenotype, mice deficient in IL1F5 were generated (see Materials and methods) and analyzed either alone or in combination with the K14/IL1F6 transgene. A similar analysis of the IL1F5-deficient mice was performed as described for the IL1R1L2-deficient mice, and no overt phenotypes, histopathological abnormalities, or immune cell changes were observed. A genetic cross was performed between K14/IL1F6, IL1F5−/− mice and IL1F5+/− mice. Genotyping of the resulting pups at 3 wk of age indicated that the K14/IL1F6, IL1F5−/− combination was dramatically underrepresented, with only 1 pup of this genotype out of 109 total pups surviving at weaning. The other three resulting genotypes (K14/IL1F6, IL1F5+/−; IL1F5−/−; and IL1F5+/+) were found in roughly equal numbers. We recovered 13 dead pups from these crosses between P5 and 10, and all 13 were K14/IL1F6, IL1F5−/−. These pups had milk in their stomachs, yet were runted and had a dehydrated appearance. Normal skin barrier function as assessed by a dye exclusion assay (33) was observed in K14/IL1F6, IL1F5−/− at both embryonic day 18.5 and P3 (unpublished data). The surviving K14/IL1F6, IL1F5−/− mouse that reached adulthood subsequently developed severe skin abnormalities. The visible skin phenotype of K14/IL1F6, IL1F5−/− and K14/IL1F6, IL1F5+/− pups was apparent by P3, whereas K14/IL1F6, IL1F5+/+ pups do not have gross skin changes until P5 (Fig. 5 A and not depicted). K14/IL1F6, IL1F5−/− pups are much smaller than their littermates and have severe skin abnormalities resembling blisters. K14/IL1F6, IL1F5+/− pups also have extensive regions of thick, scaly skin. Histological analysis reveals intracorneal and intraepithelial pustules, parakeratotic and orthokeratotic hyperkeratosis, dilated superficial dermal blood vessels, and a mixed dermal inflammatory infiltrate (Fig. 5 B). Therefore, the combination of the K14/IL1F6 transgene and IL1F5 deficiency results in increased severity of the skin phenotype and neonatal lethality.

Intraperitoneal injection of newborn K14/IL1F6, IL1F5−/− pups with 50 μg M616 at P1, 3, and 5 rescued the neonatal lethality. However, upon cessation of antibody treatment, adult K14/IL1F6, IL1F5−/− and K14/IL1F6, IL1F5+/− mice develop severe lesions on their face, neck, and ears by 4–6 wk of age. Histological analysis of the K14/IL1F6, IL1F5−/− and K14/IL1F6, IL1F5+/− adult skin demonstrates similar features as seen in the pups, with the presence of focal “plaques” interspersed with regions of normal skin (Fig. 5 C and not depicted). High magnification images in Fig. 5 D show parakeratotic hyperkeratosis and dilated superficial dermal blood vessels with a mixed inflammatory infiltrate.

**IL1R1L2, IL1F6, and IL1F5 expression is increased in human psoriatic skin**

Psoriatic plaques and nonlesional skin from 10 patients were assayed by in situ hybridization (ISH) with probes specific for human IL1R1L2, IL1F6, and IL1F5. Elevated, but low-level expression of IL1R1L2 was detected throughout the epidermis in plaques in 9/10 patients, but not in nonlesional...
No IL1RL2 expression was detected in either plaques or normal skin in the 10th patient. IL1F6 expression was strongly detected in the superficial layers of the epidermis in plaques from skin in all 10 patients, but was either not detectable or was only weakly detectable in nonlesional skin samples (Fig. 6, A and B; Table I). IL1F5 is expressed in both psoriatic plaques and in nonlesional skin from all patients (Fig. 6 C, Table I). IL1F5 expression was found throughout the epidermis, with a stronger signal in the superficial layers. IL1F5 expression appeared to be higher in plaques compared with nonlesional skin in 3/10 patients, was slightly higher in 4/10 patients, and was unchanged in 3/10 patients. IL1F5, IL1F6, and IL1RL2 expression was increased in additional psoriatic skin samples, including samples of pustular psoriasis, and in several samples of the psoriasis-like skin disease pityriasis rubra pilaris, but not in chronic eczematosus dermatitis or in nummular dermatitis (unpublished data).

To provide quantitative evidence for the association of IL1RL2, IL1F5, and IL1F6 expression with psoriasis, RT-PCR analysis was performed on seven paired psoriatic and nonlesional skin samples. Higher expression of IL1RL2, IL1F5, and IL1F6 mRNAs was observed in all psoriatic skin samples compared with their corresponding paired nonlesional skin (Fig. 6 D). In addition, there was a correlation between the expression levels of the three genes in individual patients (unpublished data). We conclude that IL1RL2, IL1F5, and IL1F6 expression is increased in psoriasis.

DISCUSSION

The IL-1 ligand superfamily has recently been expanded by the discovery of seven new members (23, 34). Three of these ligands (IL-1F6, -1F8, and -1F9) activate signaling pathways in vitro in an RP2- and AcP-dependent manner (27, 28). However, the in vivo function of these molecules has remained obscure. We demonstrate that transgenic expression of IL-1F6 in basal keratinocytes leads to skin changes affecting both the epidermis and dermis.

Figure 4. Mechanistic requirements for the K14/IL1F6 skin phenotype. An antibody against TNF-α results in decreased epidermal thickness (A) and decreased dermal inflammation ranking (B) in skin from 7-d-old K14/IL1F6 transgenic pups (n = 7) compared with K14/IL1F6 transgenic skin from pups treated with a control antibody (n = 12). (C) An antibody against CD18 (anti-Gr1) results in a decreased dermal inflammatory ranking in 7-d-old K14/IL1F6 transgenic pup skin (n = 5) compared with a control antibody (n = 6). *, P < 0.05; **, P < 0.01; ***, P < 0.001. Error bars represent the mean ± the SEM. (D) HE staining of K14/IL1F6 transgenic skin indicating a reduced dermal inflammation in anti-Gr1 antibody compared with control antibody, but no change in epidermal thickness. (E) RAG2 is not required for the skin phenotype in K14/IL1F6 pups. HE staining of skin from 7-d-old K14/IL1F6, RAG2−/− and K14/IL1F6, RAG2−/− pups is shown. IHC with anti-CD3 demonstrates the absence of mature T lymphocytes in RAG2−/− pups. IHC with anti–ICAM-1 shows that inflammation is not reduced in K14/IL1F6, RAG2−/− pups. Bar, 100 μm.
Figure 5. IL-1F5 is an antagonist of IL-1F6 in vivo. (A) K14/IL1F6 pups with reduced IL1F5 gene dosage exhibit an altered gross appearance 3 d after birth. The skin phenotype and runting are most severely affected in K14/IL1F6 Tg+; IL1F5−/− pups. From left to right: K14/IL1F6 Tg+; IL1F5−/−; K14/IL1F6 Tg−; IL1F5−/−; K14/IL1F6 Tg+; IL1F5−/−. (B) K14/IL1F6 pups with reduced IL1F5 gene dosage have a thickened epidermis, increased dermal infiltrate, and parakeratosis compared with K14/IL1F6, IL1F5+/+ pups. HE staining of skin is from 3-d-old pups. (C) Adult K14/IL1F6, IL1F5+/+ mice have skin abnormalities, whereas K14/IL1F6, IL1F5−/− mice do not. HE staining of skin is from 14-wk-old mice. (D, left) K14/IL1F6, IL1F5−/− skin exhibits parakeratotic hyperkeratosis; note the nucleated keratinocytes in the corneal layer (arrowhead). (right) K14/IL1F6, IL1F5−/− skin contains dilated superficial dermal blood vessels (arrowheads) and a mixed inflammatory infiltrate composed predominantly of neutrophils and macrophages, with fewer lymphocytes and rare eosinophils. Bars, 100 μm.

Figure 6. IL1RL2, IL1F5, and IL1F6 expression is increased in human psoriatic skin. (A) HE staining of psoriatic skin and nonlesional skin from the same patient are shown. (B) IL1F6 is up-regulated in psoriatic skin compared with nonlesional skin. IL1F6 expression is observed only in the upper spinous layer of the epidermis. (C) IL1F5 expression is detected in both psoriatic skin and nonlesional skin. However, the IL1F5 ISH signal is stronger in the psoriatic skin than in the nonlesional skin in the example shown. Green staining is autofluorescence from keratins. Bar, 100 μm. (D) Quantitative RT-PCR data for IL1RL2, IL1F5, and IL1F6 expression from psoriatic and nonlesional skin from seven patients. *, P < 0.05; **, P < 0.01; ***, P < 0.001. Error bars represent the mean ± the SEM.
K14/IL1F6 pups have skin defects with changes in both keratinocyte proliferation and differentiation. Epidermal hyperplasia is observed as demonstrated by up-regulation of K6 (Fig. 1 C) and phosphorylation of histone H3 (unpublished data) (35). K14/IL1F6 pups with decreased IL1F5 gene dosage have more severe epidermal hyperplasia than K14/IL1F6 pups with a full complement of IL1F5 (Fig. 5 B). Differentiation defects include expression of K14 in the suprabasal layer in K14/IL1F6 pups (Fig. 2 E) and parakeratosis observed in K14/IL1F6, IL1F5−/− pups (Fig. 4 D). Additionally, we have observed an increased number of CD205+ Langerhans or dermal dendritic cells, CD3+ T lymphocytes, macrophages, and neutrophils in the K14/IL1F6 pup skin. The inflammation marker ICAM-1 is increased in expression in both basal keratinocytes and in dermal cells. We have demonstrated that inhibition of TNF-α, reduction of neutrophil numbers, or the absence of mature lymphocytes cannot completely block the skin phenotype.

Alterations in the skin caused by K14/IL1F6 expression are distinct from those generated in K14/IL1A and K14/IL18 transgenic mice. Both K14/IL1F6 and K14/IL1A mice have an increase in the number of dermal macrophages, whereas only the K14/IL1F6 mice have increases in epidermal thickness and in the number of neutrophils and CD205+ cells (11). K14/IL18 mice have features resembling atopic dermatitis (12), whereas the K14/IL1F6, IL1F5−/− mice have some similarities with psoriasis, but lack several of its histological hallmarks. In addition, the K14/IL1A and K14/IL18 skin phenotypes first occur in adult mice, whereas the K14/IL1F6 skin abnormalities occur within 1 wk after birth.

An intriguing feature of the K14/IL1F6 phenotype is that it arises shortly after birth, is resolved by 3 wk of age, and then spontaneously recurs in 6-mo-old mice. Several factors may contribute to the resolution process. First, it appears that IL1F6 transgene expression is silenced by P10 (Fig. 2 E). The K14 promoter construct used does have expression differences with the endogenous KRT14 gene (unpublished data) (36). However, this K14 promoter cassette has been used to generate skin phenotypes that do not resolve (unpublished data) (36, 37). This result suggests that the observed resolution of the K14/IL1F6 skin phenotype is caused by the RP2/IL-1F axis, and not by the K14 expression cassette. Second, K14/IL1F6 expression results in increased expression in the skin of the two other agonistic ligands that activate RP2, IL-1F8 and -1F9 (Fig. 2 A).

ISH was performed on skin from 10 psoriasis patients. Both psoriatic and nonlesional skin from the same patients was analyzed. Antisense and sense probes were used, and only antisense probes gave rise to a positive signal. Staining intensity was scored from 0 (no staining) to 5.0 (very strong staining).

P5, psoriatic skin.

NLS, nonlesional skin.
that other IL-1 family ligands are also involved. In the model, IL-1F5 antagonism prevails and inflammation is minimal in the skin of wild-type mice. Shifting the balance to favor IL-1F6 agonism is proposed to result in activation of signaling through RP2/Acp, induction of cytokine and chemokine expression, and mobilization of neutrophils and macrophages into the dermis. This process is antagonized by IL-1F5. (B) Model for the critical balance between IL-1F6 and -1F5 expression in pup skin inflammation. In wild-type pups, a balance between IL-1F6 agonist activity and IL-1F5 antagonist activity results in normal skin. Increasing IL-1F6 expression by transgenic expression of an IL1F6 background tips the balance toward skin inflammation. Reducing IL1F5 gene dosage (IL1F5+/−) in the K14/IL1F6 mice exacerbates skin inflammation. Complete deletion of IL1F5 further shifts the balance in K14/IL1F6 mice, resulting in an even more severe inflammation.

MATERIALS AND METHODS

Plasmid construction. The pH2R plasmid containing the human K14 (K14) promoter was a kind gift of S. Werner (Institute of Cell Biology, Zürich, Switzerland) (37). The unique Smal cloning site for cDNA insertion was converted to an Fse1/Plae1/Ascl polylinker to create pHB137-9. Mouse IL1F6 (GenBank accession no. NM_019450) was used as a template for the polymerase chain reaction (PCR) to generate the open reading frame (166–644 in NM_019450) flanked by a 5’ Fse1 site and a consensus translation initiation sequence, and a 3’ Ascl site directly after the stop codon. This fragment was inserted in pHB137-9 digested with Fse1/Ascl to yield pHB225-1. Nucleotide sequencing confirmed that the PCR fragment was identical to the template sequence. The K14/mouse IL1F6/hGH poly A expression cassette was excised from pHB225-1 with Kpn1, to eliminate bacterial sequences from the microinjection fragment.

Generation of transgenic mice and genetic crosses. The K14/IL1F6 Kpn1 fragment was microinjected at a concentration of 2 ng/ml in 10 nM Tris and 2.1 mM EDTA, pH 9.0 in the pronucleus of mouse embryos obtained from B6D2F1 female mice bred to B6D2F1 male mice (Taconic), and implanted into pseudopregnant Swiss-Webster (Taconic) recipients. Mice were genotyped by PCR with primers in the human growth hormone (hGH) polyA region to screen for founders. Transgenic expression were determined using quantitative RT-PCR, analysis of tail skin biopsies from 7-wk-old founders. Total tail skin RNA was isolated using the RNAeasy Midi kit (Qagen). RT-PCR was performed using a Taqman Reverse Transcription Reagents kit (Applied Biosystems). Expression levels were determined by the expression of an GHI probe (Amgen) relative to GAPDH (Applied Biosystems). The highest expressers were developed into lines by backcrossing to C57BL/6 mice (Taconic). Genotyping for IL1RL2, IL1RAP, IL1R1, IL1F5, TNFRSF1A, and RAG2 was by standard PCR procedures.

Mouse sources. IL1R-deficient mice on a C57BL/6 background have been previously described (14, 15). C57BL/6 and RAG2-deficient mice (B6.129S6–RAG2<sup>−/−</sup>) were obtained from Taconic. IL1RAP-deficient mice (B6; 129S1–1<sup>Il1rap<sup>tm1Fwa N12</sup></sup>) were obtained from Jackson ImmunoResearch Laboratories. Mice lacking IL1RL2 and IL1F5 were generated by homologous recombination in 129-derived ES cells (Lexicon Genetics). In brief, exons 1–3 of the IL1F5 gene and exons 2–4 of the IL1RL2 gene were replaced with a lacZneo cassette. Targeted ES clones were identified by Southern blot analyses and injected into C57BL/6 blastocysts. The resulting chimeras were crossed to C57BL/6 to generate B6;129 F1 heterozygotes, which were intercrossed to generate B6;129 F2 homozygotes. The mutants used throughout these studies are on a random hybrid B6;129 genetic background. All protocols used in these studies were in compliance with federal guidelines and the Amgen Institutional Animal Care and Use Committee.

Quantitative RT-PCR expression analysis. Quantitative RT-PCR was performed using a Taqman Reverse Transcription Reagents kit (Applied Biosystems). Expression levels for the following genes were determined by their expression using the following primers and probes, which were designed in-house (Amgen) relative to mouse ACTB (Applied Biosystems): IL1F5, IL1F6, IL1F8, IL1F9, IL1RL2, IL23A, CSF2, and IL1A. Predesigned Taqman Gene Expression Assays (Applied Biosystems) were used for the following genes: IL1RAP, TNF, CCL2, KRT14, CXCL2, TGA2, HBEGF, and AREG.

Histopathological analysis. Standard histopathological examination was performed on skin samples fixed in 10% neutral buffered formalin, formalin routinely, and stained with hematoxylin and eosin (HE). IHC was performed on selected skin sections using the following antibodies: 2.5 μg/ml K6 (Covance), 50 ng/ml K14 (Covance), 2 μg/ml CD54 (ICAM-1; Millipore), 10 μg/ml CD205 (DEC205; Serotec), 5 μg/ml CD3 (DakoCytomation), 20 μg/ml F4/80 (BM8; Serotec), and 15 μg/ml IL-1F6 (Amgen). IHC for CD54 and CD205 were performed on skin samples fixed with Zinc-Tris buffer (0.1 M Tris, pH 7.4) rather than formalin because of sensitivity of the antigens to protein cross-linking. All other antibodies were used on formalin-fixed, paraffin-embedded samples. IHC for keratin 6 and F4/80 required antigen retrieval for 5 min with protease K.

Epidermal thickness was measured on formalin-fixed, paraffin-embedded samples of back skin stained with HE. For each animal, a digital photographic image was taken using the 20X microscope objective in the area of maximal epidermal thickening, and the epidermal thickness from the bottom of the keratin layer to the epidermal basement membrane was measured in micrometers at three locations on each image using the caliper function of MetaVue morphometry software (Universal Imaging Corporation). The three measurements were averaged to determine the maximal epidermal thickness for each animal. The group mean and SD were calculated using the mean epidermal thickness for each individual as a single value. Skin samples were blinded and mixed randomly before image field selection and while taking epidermal measurements. Inflammation severity ranking was done on
Antibodies used in the treatment of K14/IL1F6 pups. M616, which is a rat IgG2a anti–mouse RP2 blocking antibody, was generated at Amgen. 3F8, which is a rat IgG2a isotype-matched control antibody raised against an irrelevant protein, was also generated at Amgen. Purified rat anti–mouse Ly-6G and Ly-6C (Gr-1, IgG2b, k isotype) was purchased from BD PharMingen. Purified rat IgG1, k isotype-matched control antibody was purchased from BD PharMingen. TN3-19.12, which is a hamster antibody against mouse TNF-α, was purchased from eBioscience. The control antibody for TN3-19.12 was hamster IgG (Pierce Chemical Co.).

Half of the litter was tail snipped so that we could distinguish pups treated with test antibody from those treated with control antibody. Newborn pups were injected intraperitoneally with either 50 µg M616 or with 50 µg of an isotype-matched control antibody (3F8) starting 1 d after birth, every other day for 1 wk. Pups were scored at P7 for a visible skin phenotype and killed, and skin was collected for histopathological analysis. Similar experiments were performed with anti–mouse Ly-6G/Ly-6C (anti-Gr1) versus control antibody, and for anti–TNF-α (TN3-19.12) versus hamster IgG in newborn K14/IL1F6 pups.

Quantitation of cytokine and chemokine levels in skin protein extracts. Back skin from individual pups was isolated and immediately frozen in liquid nitrogen. Tissue was converted into powder using a Bismann Tissue Pulverizer (Fisher Scientific). Extracts were homogenized in ice-cold digestion buffer (50 mM Tris, pH 7.4 containing 0.1 M NaCl and 0.1% Triton X-100). The homogenate was centrifuged at 15,000 rpm for 20 min, aliquoted, and stored at −20°C until further analysis. Skin protein extracts were normalized by BCA total protein quantitation kit (Pierce Chemical Co.). Multiple analyte panel (MAP) analysis on skin protein extracts was performed by Rugs Based Medicine using Luminex technology. MAP results for specific analytes were validated by ELISA analysis. Mouse MIP-2, GM-CSF, MCP-1, IL-6, and KC were quantified using duosets (R & D Systems) for specific analytes were validated by ELISA analysis. Mouse MIP-2, GM-CSF, MCP-1, IL-6, and KC were quantified using duosets (R & D Systems) for specific analytes were validated by ELISA analysis. Mouse MIP-2, GM-CSF, MCP-1, IL-6, and KC were quantified using duosets (R & D Systems) for specific analytes were validated by ELISA analysis.

ISH. A standard ISH protocol was performed using antisense 35P-labeled RNA probes synthesized by in vitro transcription of the template with either T3 or T7 RNA polymerase after linearization of the vector with an appropriate restriction enzyme. The human IL1F3 probe was 581 nt long, from 131–712, in GenBank accession no. NM_012275. The human IL1F6 probe was 477 nt long, from 1–477, in GenBank accession no. AF20831. The human IL1RL2 probe was 1,005 nt long, from 133–1,139, in GenBank accession no. AF284434. Probes were hybridized to tissue sections overnight at 60°C, followed by RNase digestion to remove unhybridized probe and a series of washes, with the highest stringency being 0.1× SSC at 55°C for 30 min. The slides were coated with Kodak NTB2 emulsion and exposed for 3 wk in the dark at 0–4°C, developed, and then counterstained with HE.

Statistical analysis. All statistical calculations were performed using SAS software version 9.1 (SAS Institute, Inc.). In Fig. 1 D, P values were calculated from two-sample t tests with unequal variances and further adjusted by Bonferroni procedure for multiple comparisons. In Fig. 1 E, log transformation was applied to the epidermal thickness to improve normality. The nonparametric approach was applied when log transformation failed to improve the normality. P values were calculated from mixed effect models, including genotype and ID (animal) as random effect for each time point. P values were adjusted by Bonferroni procedure for multiple comparisons. In Fig. 2 (A–C), log transformation was applied to the 2E-DCT measurement to improve normality. Differences in gene expression between genotype groups were conducted using analysis of variance by contrasting at each time point. The resultant P values were adjusted using the stepdown Sidak procedure for multiple comparisons by each gene. In Fig. 4 A, P value was calculated by analysis of variance and contrasting between indicated groups. In Fig. 4 (B and C), the effect of genotype on dermal inflammation ranking was tested by a two-sample t test. In Fig. 6 D, log transformation was applied to the 2E-DCT to improve normality. Paired t tests were used for comparison between PS and NLS on log-transformed IL1RL2 and IL1F5 data. A Wilcoxon signed rank test was used for F6 because of the nonnormal distribution of the data.

We are grateful to Sabine Werner for providing the plasmid containing the human K14 promoter. We thank the following colleagues for their contributions: Dan Branstetter, Bernie Buetow, Keith Charrier, Guang Chen, Mike Comeau, Taska Dolson, Barbara Felder, Chris Gabel, Moira Glaccum, Kari Hale, Deanna Hill, Tenzin Jigme, Keith Kerkoff, Bill Lawrence, Melissa Lee, Michelle Pace, Lori Petersen, Blair Rerasher, Dirk Smith, Cheng Su, and Jeffrey Williams. We acknowledge generation of the IL1RL2- and IL1F5-deficient mice by Lexicon Genetics. We thank the Inflammation Therapeutic Area at Amgen for critical analysis of this work. We dedicate this manuscript to the memory of our colleague Brad Sevetson.
