It has been recently shown (Seddiki, N., B. Santner-Nanan, J. Martinson, J. Zaunders, S. Sasson, A. Landay, M. Solomon, W. Selby, S.I. Alexander, R. Nanan, et al. 2006. J. Exp. Med. 203:1693–1700.) that the expression of interleukin (IL) 7 receptor (R) α discriminates between two distinct CD4 T cell populations, both characterized by the expression of CD25, i.e. CD4 regulatory T (T reg) cells and activated CD4 T cells. T reg cells express low levels of IL-7Rα, whereas activated CD4 T cells are characterized by the expression of IL-7Rα high. We have investigated the distribution of these two CD4 T cell populations in 36 subjects after liver and kidney transplantation and in 45 healthy subjects. According to a previous study (Demirkiran, A., A. Kok, J. Kwekkeboom, H.J. Metselaar, H.W. Tilanus, and L.J. van der Laan. 2005. Transplant. Proc. 37:1194–1196.), we observed that the T reg CD25⁺CD45RO⁺IL-7Rα low cell population was reduced in transplant recipients (P < 0.00001). Interestingly, the CD4⁺CD25⁺CD45RO⁺IL-7Rα high cell population was significantly increased in stable transplant recipients compared with healthy subjects (P < 0.00001), and the expansion of this cell population was even greater in patients with documented humoral chronic rejection compared with stable transplant recipients (P < 0.0001). The expanded CD4⁺CD25⁺CD45RO⁺IL-7Rα high cell population contained allospecific CD4 T cells and secreted effector cytokines such as tumor necrosis factor α and interferon γ, thus potentially contributing to the mechanisms of chronic rejection. More importantly, CD4⁺IL-7Rα+ and CD25⁺IL-7Rα+ cells were part of the T cell population infiltrating the allograft of patients with a documented diagnosis of chronic humoral rejection. These results indicate that the CD4⁺CD25⁺IL-7Rα+ cell population may represent a valuable, sensitive, and specific marker to monitor allospecific CD4 T cell responses both in blood and in tissues after organ transplantation.

The antillograft immune response remains an important cause of acute rejection and late graft dysfunction in solid organ transplantation. In addition to the clinical and pathological manifestations of graft dysfunction, various biological markers have been investigated to monitor graft rejection over the years. De novo donor-specific anti-HLA antibodies represent a valuable marker, as their development is generally associated with rejection (1). However, T cell immunity plays a pivotal role in graft rejection (2). In this regard, a series of biological markers related to the inflammatory response, such as cytokines, thromboxane B2, β2 microglobulin (3, 4), and other phenotypic and functional markers associated with T cell activation such as IL-2Rα (CD25) expression, CD69, HLA-DR (5–8), cell proliferation, cytokine secretion, and cytotoxicity (9–12), have been evaluated to monitor cell-mediated immunity. However, these markers are neither sensitive nor specific, and their...
measurement may be technically complex and time-consuming. For these reasons, none of these markers is routinely used in the monitoring of transplant recipients.

It has been recently reported that regulatory CD4 T cells (i.e., T reg cells) express low levels of IL-7Rα compared with other CD4 T cell subsets (13–17), and it has been proposed that IL-7Rα can be used to discriminate between T reg cells and activated CD4 T cells within the CD4+CD25+ cell population (15, 17). The CD4+CD25+ IL-7Rαhigh cell population contains activated T cells and is poorly represented (~5% within CD4+CD25+ T cells) in healthy subjects. Conversely, after transplantation, both activated allospecific CD4 T cells and T reg cells may play a critical role by either participating in allograft rejection or promoting tolerance (18–25).

In this study, we have searched for sensitive and highly specific cellular markers that may define the population of allospecific CD4 T cells to quantify this cell population after transplantation, to monitor possible changes, and to determine the pattern of the allospecific population in chronic graft rejection. We demonstrate that a CD4 T cell population defined by the CD25+CD45RO+IL-7Rαhigh phenotype contains allospecific cells and is expanded in the blood of stable transplant recipients and even further expanded in patients with a documented diagnosis of chronic rejection. In these latter patients, CD4+CD25+ IL-7Rα cells were a major component of T cells infiltrating the allograft.

RESULTS AND DISCUSSION

Distribution of CD4+CD25+ T cell populations defined by the expression of IL-7Rα (i.e., IL-7Rαlow vs. IL-7Rαhigh) in stable organ transplant recipients

We have studied the distribution of T reg cells and activated CD4 T cells in blood mononuclear cells of 32 stable transplant recipients, 21 liver and 11 kidney transplant recipients, and 4 patients with documented chronic kidney rejection, as well as 45 healthy subjects.

In accordance with recent studies (15, 17), the majority (88.2%) of CD4+CD25+ T cells were CD45RO+FOXP3+ and IL-7Rαlow in a representative healthy subject (1 out of 45), as shown in Fig. 1 A. This is the typical phenotype of T reg cells (26–28). Only a small percentage (3.1% in the example shown in Fig. 1 A) of CD4+CD25+ T cells expressed IL-7Rαhigh, and these cells were FOXP3 negative. We then performed the same analysis in stable transplant recipients. In one representative stable liver transplant recipient (1 out of 32), the CD4+CD25+CD45RO+FOXP3+IL-7Rαlow cell population was reduced (66.1%; Fig. 1 A) compared with the representative healthy subject. Interestingly, we observed a major increase (29.1%) in the CD4+CD25+CD45RO+FOXP3+IL-7Rαhigh cell population (Fig. 1 A). The differences in the distribution of IL-7Rαlow and IL-7Rαhigh within the CD4+CD25+CD45RO+ cell population between healthy subjects and stable transplant recipients were confirmed by the analysis of a larger number of subjects.

In agreement with a previous report (25), the percentage of total CD4+CD25+ T cells was significantly reduced (P < 0.00001) in stable transplant recipients receiving immunosuppressive therapy compared with healthy subjects. The reduction was in the range of 40%; the mean percentage of CD4+CD25+ T cells was 2.23 ± 0.12% in healthy subjects (n = 45) compared with 1.31 ± 0.14% in stable transplant recipients (n = 32; Fig. 1 B).

The analysis of IL-7Rα and FOXP3 expression allowed the discrimination between T reg cells (26–28) and activated CD4 T cells. This analysis showed that the percentage of T reg cells (the IL-7RαlowFOXP3+ cell population) was significantly lower (P < 0.00001) in stable transplant recipients (mean = 62 ± 1.54%) compared with healthy subjects (mean = 29.37 ± 2.33%; Fig. 1 B). Therefore, these results indicate that the reduction in T reg cells in stable transplant recipients is even greater than that estimated on the basis of the analysis of total CD4+CD25+ T cells. Furthermore, the population of activated CD4 T cells (i.e., the CD4+CD25+CD45RO+IL-7Rαhigh cell population) was greatly expanded (mean = 18.38 ± 1.05%) in stable transplant recipients compared with healthy donors (mean = 6.16 ± 0.76%; Fig. 1 B). These differences were highly significant (P < 0.00001). On the basis of the present results and of recent studies (15, 17), we then analyzed the correlation between IL-7Rα and FOXP3 expression in CD4+CD25+ T cells in stable transplant recipients. This analysis confirmed a negative correlation between IL-7Rα and FOXP3 expression in CD4+CD25+ T cells (Fig. 1 C). The IL-7Rαlow cells were contained within the FOXP3+ positive cell population, whereas IL-7Rαhigh cells were within the FOXP3-negative cell population (Fig. 1 C). Collectively, these results indicated that IL-7Rα is a valuable marker to discriminate between T reg cells and activated CD4 T cells within the CD4+CD25+ T cell population in stable recipients of organ transplants.

Next, it was of interest to determine the suppressive activity of CD4+CD25+CD45RO+IL-7Rαlow and IL-7Rαhigh cells. For these purposes, sorted purified IL-7Rαlow and IL-7Rαhigh cell populations isolated from stable transplant recipients were assessed for their suppressive activity in a mixed lymphocyte reaction (MLR). The IL-7Rαlow cell population (T reg cells) strongly suppressed the MLR (83% inhibition of proliferation; P = 0.02), whereas the IL-7Rαhigh cell population did not show any significant suppressive activity (P = 0.2; Fig. 1 D). These results obtained in stable transplant recipients are in agreement with those previously shown in healthy individuals (15, 17). Furthermore, the CD4+CD25+CD45RO+IL-7Rαhigh cell population was also evaluated for the ability to secrete cytokines such as IFN-γ and TNF-α after polyclonal stimulation with anti-CD3 plus anti-CD28 antibodies. This analysis performed in blood mononuclear cells of 29 stable transplant recipients showed that a substantial percentage of CD4+CD25+CD45RO+IL-7Rαhigh cells secreted inflammatory cytokines, such as TNF-α (~15%) and IFN-γ (~4%), that may be involved in the mechanisms of chronic rejection (Fig. S1, http://www.jem.org/cgi/content/full/jem.20062120/DC1). Collectively, these results indicated that the CD4+CD25+CD45RO+IL-7Rαhigh cell population...
does not contain T reg cells and suggested that the expansion of this cell population in transplant recipients is associated with the presence of the allograft.

**Larger expansion of the CD4⁺CD25⁺CD45RO⁺IL-7Rα\(^{\text{high}}\) cell population in transplant recipients with chronic rejection**

To better support this hypothesis, we examined the presence of the CD4⁺CD25⁺CD45RO⁺IL-7Rα\(^{\text{high}}\) cell population in kidney transplant recipients with documented chronic humoral rejection. The total CD4⁺CD25⁺ T cell population was not significantly different in kidney recipients with documented chronic rejection compared with stable transplant recipients (mean \(7.05\% \pm 3.43\%\) vs. \(18.38\% \pm 5.8\%) compared with stable transplant recipients (mean \(62.02\% \pm 3.43\%\) vs. \(18.38\% \pm 1.05\%\); Fig. 2 C). These differences were highly significant (\(P < 0.0001\)).

When the CD4⁺CD25⁺CD45RO⁺IL-7Rα\(^{\text{high}}\) population from patients with chronic rejection was compared with the one of stable kidney transplant recipients, the difference was also significant (\(P = 0.0003\); unpublished data). Therefore,

**Figure 1. Expression of CD25, CD45RO, IL-7Rα, and FOXP3 on blood CD4 T cells of healthy subjects and stable transplant recipients.**

Blood mononuclear cells from 45 healthy subjects and 32 stable organ transplant recipients (11 kidney and 21 liver transplant recipients) were analyzed for the surface expression of CD4, CD25, CD45RO, and IL-7Rα and for the intracellular expression of FOXP3. (A) Surface expression of CD45RO and IL-7Rα in CD4⁺CD25⁺ T cells. Representative flow cytometry profiles of one healthy donor (1 out of 45; top) and one stable liver transplant recipient (1 out of 32; bottom). The vast majority of CD4⁺CD25⁺ T cells are CD45RO⁺IL-7Rα\(^{\text{low}}\) and FOXP3⁺ in the healthy donor, while a substantial percentage of CD4⁺CD25⁺ T cells are CD45RO⁺IL-7Rα\(^{\text{high}}\) and FOXP3⁻ (green) in the stable transplant recipient. (B) Cumulative data on the proportion of CD4⁺CD25⁺ T cells (top left), CD4⁺CD25⁺FOXP3⁺ IL-7Rα\(^{\text{low}}\) T cells (top right), and CD4⁺CD25⁺CD45RO⁺IL-7Rα\(^{\text{high}}\) T cells (bottom) in stable transplant recipients and healthy donors. (C) Correlation between the expression of FOXP3 and IL-7Rα within CD4⁺CD25⁺ T cells. The percentage of FOXP3⁺ T cells correlated with that of IL-7Rα\(^{\text{low}}\) cells within CD4⁺CD25⁺ T cells, and the percentage of FOXP3⁺ T cells correlated with that of IL-7Rα\(^{\text{high}}\) cells within CD4⁺CD25⁺ T cells. The analyses were performed in 26 stable transplant recipients. In both cases, these correlations were statistically significant (\(P < 0.005\)). (D) Suppressive activity of IL-7Rα\(^{\text{low}}\) and IL-7Rα\(^{\text{high}}\) CD4⁺CD25⁺CD45RO⁺ T cell populations in stable transplant recipients. CD4⁺CD25⁺CD45RO⁺IL-7Rα\(^{\text{high}}\) and CD4⁺CD25⁺CD45RO⁺IL-7Rα\(^{\text{low}}\) cell populations were sorted from blood mononuclear cells of five stable liver transplant recipients, and their suppressive activity was evaluated in a MLR. The extent of cell proliferation in a MLR was assessed in the absence (positive control) or in presence of the sorted IL-7Rα\(^{\text{low}}\) and IL-7Rα\(^{\text{high}}\) cell populations. Cell proliferation was measured by \([\text{H}]\)thymidine incorporation. The data shown are expressed as the mean ± SE and were obtained from five independent experiments.
although the expansion of the $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cell population in patients with chronic rejection was associated with a decrease of T reg cells, the reduction of the T reg cell population was not sufficient to explain the increase of the $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cell population, thus indicating an absolute increase in the number of this latter population. Indeed, the absolute number of $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cells was also significantly increased ($1.5 \pm 0.4 \times 10^3$ cells per 100 µl of blood) in patients with chronic rejection compared with stable transplant recipients ($0.8 \pm 0.1 \times 10^3$ cells per 100 µl of blood; $P = 0.04$). However, the absolute number of T reg cells did not significantly change between the stable transplant recipients ($3.8 \pm 0.5 \times 10^3$ cells per 100 µl of blood) and the patients with chronic rejection ($3 \pm 0.5 \times 10^3$ cells per 100 µl of blood; $P = 0.3$).

Collectively, these results indicate (a) an association between the presence of an expanded $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cell population and the occurrence of chronic allograft rejection, and that (b) the expansion of the activated $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cell population defined by the expression of IL-7Rα cannot be explained only by the result of the decrease of the T reg cell population defined by the expression of FOXP3. Therefore, monitoring IL-7Rα may be a more valuable tool than monitoring FOXP3 to assess the patient’s immune status and/or the occurrence of allograft chronic rejection.

The $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cell population contains allospecific $CD4$ T cells

To have insights on the possible involvement of the $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cell population in the allospecific response to the graft, we examined the allospecific response of the transplant recipient to the donor in a MLR. Indeed, we had the opportunity to address this issue in a case of documented kidney chronic humoral rejection in which blood mononuclear cells of the (living) donor were available. The $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cell population was largely expanded ($\sim 40\%$ of the $CD4^+CD25^+$ T cells) at the time of the diagnosis of chronic humoral rejection (time point 1; Fig. 3). The MLR was performed using the transplant recipient–sorted $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cells mixed with irradiated transplant donor or MHC unrelated mononuclear cells. Interestingly, we found that the proliferation of the $CD4^+CD25^+CD45RO^+IL-7R\alpha_{\text{high}}$ cell population was substantially higher (stimulation index [SI] = 66) in the presence of irradiated transplant donor blood mononuclear cells compared with the proliferation in the presence of MHC unrelated blood mononuclear cells (SI = 13; Fig. 3). Because of the diagnosis of chronic humoral rejection, this

![Figure 2](Image 96x266 to 264x708)

**Figure 2.** Expression of CD25, CD45RO, IL-7Rα, and FOXP3 on blood CD4 T cells of stable transplant recipients and kidney transplant recipients with chronic rejection. Blood mononuclear cells from 32 stable transplant recipients (11 kidney and 21 liver transplant recipients) and 4 kidney transplant recipients with biopsy-proven chronic rejection were analyzed for the surface expression of CD4, CD25, CD45RO, and IL-7Rα and for the intracellular expression of FOXP3. (A) Means ± SE of cumulative data on the proportion of CD4+$\times 10^3$ cells per 100 µl of blood) and the pa-

- T cells in stable transplant recipients and transplant recipients with chronic rejection. The proportion of CD45RO+$\times 10^3$ cells within the CD4+$\times 10^3$ cells population was significantly increased in the chronic rejection group compared with the stable group ($P < 0.0001$).
were co-cultured with 10^5 irradiated blood mononuclear cells (40 Gy) either from the organ donor or from an MHC unrelated subject. After 7 d of culture, cell proliferation was measured by [H]thymidine incorporation. Cells cultures containing only irradiated cells were used as negative controls.

In support of the association between the magnitude of transplant rejection and the IL-7Rα high cell population during the first year after transplantation in 11 kidney transplant recipients, we recently had the opportunity to prospectively monitor the CD4 T cells infiltrating the kidney tissue allograft. Five patients with a documented diagnosis of chronic humoral rejection. For this purpose, frozen kidney biopsies were simultaneously stained with the following antibody combinations: CD4 plus CD25, CD4 plus IL-7Rα, CD45RO plus IL-7Rα, CD4 plus FOXP3, IL-7Rα plus FOXP3, and CD25 plus FOXP3. Variable numbers of cells infiltrating the allograft were consistently found in all of the cases studied. Of interest, with regard to CD4 T cells, ~20% were CD25^+ and ~50% were IL-7Rα^+; all CD25^+ cells coexpressed IL-7Rα (Fig. 4A). The estimates of the percentage of infiltrating CD4^+CD25^+ and CD4^+IL-7Rα^+ cells have been generated from counting ~80 infiltrating CD4 T cells in 18 different microscopic fields of the five kidney biopsies. We also investigated the expression of FOXP3 in the CD4 T cells infiltrating the allograft, but CD4^+FOXP3^+ cells were not found in the five kidney biopsies examined (Fig. 4B). However, CD4^+FOXP3^+ cells were consistently found in the lymph node biopsies used as control tissue (Fig. 4C). It is also worth mentioning that cellular infiltrates were very scarce in the biopsy of patients with a kidney disease such as interstitial nephritis, and in this case, infiltrating CD4 T cells were CD25^− and IL-7Rα^− (unpublished data). Therefore, these results indicate that the predominant CD4 T cell population infiltrating the allograft in patients with chronic rejection is composed of CD4^+CD25^+ and CD4^+IL-7Rα^+ cells.

### CD4^+CD25^+IL-7Rα^+ cells infiltrate the allograft

We investigated the phenotype of the cells infiltrating the kidney tissue allograft in five patients with a documented diagnosis of chronic humoral rejection. For this purpose, frozen kidney biopsies were simultaneously stained with the following antibody combinations: CD4 plus CD25, CD4 plus IL-7Rα, CD45RO plus IL-7Rα, CD4 plus FOXP3, IL-7Rα plus FOXP3, and CD25 plus FOXP3. Variable numbers of cells infiltrating the allograft were consistently found in all of the cases studied. Of interest, with regard to CD4 T cells, ~20% were CD25^+ and ~50% were IL-7Rα^+; all CD25^+ cells coexpressed IL-7Rα (Fig. 4A). The estimates of the percentage of infiltrating CD4^+CD25^+ and CD4^+IL-7Rα^+ cells have been generated from counting ~80 infiltrating CD4 T cells in 18 different microscopic fields of the five kidney biopsies. We also investigated the expression of FOXP3 in the CD4 T cells infiltrating the allograft, but CD4^+FOXP3^+ cells were not found in the five kidney biopsies examined (Fig. 4B). However, CD4^+FOXP3^+ cells were consistently found in the lymph node biopsies used as control tissue (Fig. 4C). It is also worth mentioning that cellular infiltrates were very scarce in the biopsy of patients with a kidney disease such as interstitial nephritis, and in this case, infiltrating CD4 T cells were CD25^− and IL-7Rα^− (unpublished data). Therefore, these results indicate that the predominant CD4 T cell population infiltrating the allograft in patients with chronic rejection is composed of CD4^+CD25^+ and CD4^+IL-7Rα^+ cells.

### Importance of the analysis of the CD4^+CD25^+CD45RO^+ IL-7Rα high cell population in the clinical monitoring of transplant recipients

In this study, the results shown in Figs. 1 and 2 demonstrating the expansion in blood of the CD4^+CD25^+CD45RO^+IL-7Rα high cell population were obtained from a cross-sectional analysis performed in 32 (21 liver and 11 kidney) organ transplant recipients. We recently had the opportunity to prospectively monitor the CD4^+CD25^+CD45RO^+IL-7Rα high cell population during the first year after transplantation in 11 kidney recipients receiving calcineurin-based immunosuppression with tacrolimus and mycophenolate mofetil (Fig. 5).
EXPANSION OF CD4+CD25+IL-7RαHIGH CELLS IN TRANSPLANTATION | Codarri et al.
At study entry (before transplantation), there were no differences in the percentage of CD4+CD25+CD45RO+IL-7Rαhigh cells between the transplant recipients and living donors. The mean percentage in transplant recipients (5.04 ± 0.75%) and in living donors (4.65 ± 0.7%) was consistent with that observed in the large cohort of healthy subjects (n = 45; 6.16 ± 0.76%; Fig. 5). Of interest, the CD4+CD25+CD45RO+IL-7Rαhigh cell population was significantly increased (up to ~14% of the CD4+CD25+ T cells; P < 0.005) 1 mo after transplantation as compared with study entry, and the activated cell population remained expanded during the year of observation (Fig. 5). Interestingly, kidney allograft function in these recipients was stable during the study period, and there was no evidence of allograft rejection. These data further support the relationship between the expansion of the IL-7Rαhigh CD4 T cell population and the presence of the allograft and the usefulness of implementing the determination of this cellular marker in the immunologic monitoring of the transplant recipients.

CONCLUSIONS

We have identified the presence of a CD4 T cell population that is selectively expanded in patients after organ transplantation and is phenotypically defined by the expression of CD25, CD45RO, and high levels of IL-7Rα. Of interest, this cell population is expanded in stable transplant recipients in the absence of measurable circulating anti-HLA antibodies, thus indicating that it represents an allospecific cellular marker to monitor the immune response against the allograft. More importantly, this cell population contains allospecific CD4 T cells, it is substantially more expanded in patients with documented chronic humoral rejection, and ~50% of the CD4 T cells infiltrating the allograft (in the case of chronic rejection) are IL-7Rα+. Collectively, these results suggest that the CD4+CD25+IL-7Rα+ cell population represents a valuable, sensitive, and specific marker to monitor allospecific CD4 T cell responses in blood and tissue after organ transplantation. The precise contribution of this activated T cell population on the induction of effector mechanisms of late, chronic allograft rejection (e.g., production of alloantibodies with local complement activation) remains to be further studied. The clinical usefulness of this novel cellular marker in the monitoring of allograft recipients and its relationship with clinical outcomes need to be investigated in large prospective cohort studies of organ transplant recipients.

Figure 5. Rapid expansion of the CD4+CD25+CD45RO+IL-7Rαhigh cell population after transplantation. Means ± SE of cumulative data on the proportion of the CD4+CD25+CD45RO+IL-7Rαhigh T cell population in transplant recipients before and up to 1 yr after transplantation. At the baseline (before transplantation), recipients and donors have a similar proportion of CD4+CD25+CD45RO+IL-7Rαhigh T cells. The IL-7Rαhigh CD4 T cell population is already significantly increased 1 mo after transplantation in the transplant recipients and remains expanded for up to 1 yr.

MATERIALS AND METHODS

Patients. 21 liver and 15 kidney transplant recipients were studied at the Centre Hospitalier Universitaire Vaudois. All patients gave informed written consent before participating in the study, which was approved by the local institutional review board. 45 healthy volunteers were included as controls.

Peripheral blood was obtained from 21 clinically stable liver transplant recipients, all of whom had received a first cadaveric graft and were studied for >12 mo after transplantation. This group was composed of 15 males and 6 females, with a median age of 51.2 yr (range = 20–67 yr) at the time of the study and a median time from transplantation to the study of 7.6 yr (range = 1–19 yr). Their immunosuppressive therapy was based on cyclosporine or tacrolimus with prednisone (n = 7) in combination with mycophenolate mofetil or azathioprine (n = 2).

Peripheral blood was also obtained from 15 kidney transplant recipients divided into two groups: (a) 11 patients with a stable graft function defined by a stable serum creatinine with values inferior to 150 μmol/liter and by a 24-h proteinuria inferior to 0.5 g/day, and (b) 4 patients with biopsy-proven chronic rejection. The stable kidney group was composed of seven males and four females, with a median age of 48.8 yr (range = 24–70 yr) at the time of the study and a median time from transplantation to the study of 8.6 yr (range = 1–19 yr). All patients had received a first graft: eight from a deceased donor, two from a
living/related donor, and one from a living/unrelated donor. No patient in this group had circulating anti-HLA antibodies. The chronic rejection group was composed of two males and two females, with a median age of 42.8 yr (range = 26–56 yr) at the time of the study and a median time from transplantation to the study of 9 yr (range = 6–16 yr). Also in this group, patients had received a first graft: three from a deceased donor and one from a living/related donor (father to daughter). In the four patients with biopsy-proven chronic rejection (29, 30), circulating donor-specific anti-HLA antibodies (DSA) were detected in serum by ELISA (One Lambda, Inc.), and capillary C4d deposits were demonstrated in kidney graft biopsies. In three out of four biopsies, typical lamination with multilayering of the basement membrane of peritubular capillaries was also demonstrated by electron microscopy. In the living/donor recipient with chronic rejection, a repeat B cell cross match was positive (T and B cell cross matches were negative at the time of transplantation). In all four patients, circulating DSA were directed against defined class II antigens (anti-class II DSA). The median serum creatinine at the time of diagnosis of chronic rejection was 247 ± 300 μmol/liter (range = 184–350 μmol/liter), whereas the median 24-h proteinuria was 2.1 g/day (range 23–81 yr) at the time of study. The patients received various regimens of immunosuppressive drugs.

The group of patients with various autoimmune diseases studied at the Centre Hospitalier Universitaire Vaudois was composed of one male and six females, with a median age of 37.9 yr (range = 21–55 yr) at the time of the donation. All of these 11 kidney transplant recipients received a first graft: three from a deceased donor and one from a living/donor (living donor) was composed of two males and nine females, with a median age of 52.8 yr (range = 32–73 yr) at the time of the donation. All of these 11 transplant recipients received a 3–4-d thymoglobulin (1.5 mg/kg) course as induction therapy, with a calcineurin-based immunosuppressive regimen.

The group of patients with various autoimmune diseases studied at the Centre Hospitalier Universitaire Vaudois was composed of one male and six females, with a median age of 37.9 yr (range = 21–55 yr) at the time of the study. The patients received various regimens of immunosuppressive drugs.

FACS analysis and sorting. Peripheral blood mononuclear cells were isolated using standard Ficoll-Hypaque (GE Healthcare) gradient centrifugation. The antibodies used for flow cytometric analyses included PerCP, PerCP-Cy5.5, or PE-conjugated mouse anti-human CD4 (Becton Dickinson); allophycocyanin (APC)-conjugated mouse anti-human CD25 (BD Biosciences), FITC (BD Biosciences), or ECD (Beckman Coulter)-conjugated mouse anti-human CD45RO; and PE (Beckman Coulter)- or APC (R&D Systems)-FITC (BD Biosciences), or ECD (Beckman Coulter)-conjugated mouse anti–human CD25 (BD Biosciences), Cy5.5, or PE-conjugated mouse anti–human CD4 (Becton Dickinson); allo- lated using standard Ficoll-Hypaque (GE Healthcare) gradient centrifugation.

Peripheral blood mononuclear cells were isolated from the peripheral blood of liver transplant recipients was prestained with anti-IL-7Rα PE and mouse anti–human CD25 PE-Cy7 (BD Biosciences) antibodies and stimulated overnight with soluble 1 μg/ml anti-CD3 plus 1 μg/ml anti-CD28 antibodies (BD Biosciences) in 1 ml of complete medium (RPMI plus 10% FBS) containing 1 μl/μl each of GolgiPlug and GolgiStop (BD Biosciences). At the end of the stimulation period, the cells were washed and stained with CD4 PerCP-Cy5.5 and CD45RO ECD antibodies. The cells were permeabilized with FACS Permeabilizing Solution 2 (BD Biosciences) and stained with mouse anti-human IFN-γ or TNF-α FITC and rat anti- human IL-2 APC (BD Biosciences). Data were acquired on an LSRII and analyzed using DiVa software (Becton Dickinson). Unstimulated cells were used as negative control for the production of cytokines. The background never exceeded 0.02%.

Immunohistochemistry. Frozen tissues from kidney biopsies were incubated at room temperature for 20 min with a blocking solution (5% normal goat serum) and immediately stained overnight at 4°C with a mix of primary antibodies: IgG1 mouse anti-human IL-7Rα (BD Biosciences) with IgG2a mouse anti-human CD4 (Beckman Coulter) or with IgG2b rat anti-human CD25 (Serotec) and mouse anti-human CD4 with rat anti–human CD25. The tissues were also stained with IgG2a rat anti-human FOXP3 (eBioscience) and IgG1 mouse anti–human CD4 (BD Biosciences) or IgG1 mouse anti–human CD25 (BD Biosciences) or mouse anti–human IL-7Rα. Secondary antibodies (goat IgG specific) were added after 16 h (after washing the unbound primary antibodies) and incubated for 1 h at room temperature in the dark. Goat anti–mouse IgG1 Alexa Fluor 488, goat anti–mouse IgG2a Alexa Fluor 594, goat anti–mouse IgG (H+L) Alexa Fluor 532, goat anti–rat IgG (H+L) FITC, biotinylated goat anti–rat Ig (H+L), streptavidin Texas red, and streptavidin FITC were all obtained from Invitrogen. The tissues were mounted with antifade reagent (ProLong Gold; Invitrogen) and observed on an imaging microscope (Axioplan 2; Carl Zeiss MicroImaging, Inc.) with epifluorescence using single-band excitation filters: Alexa Fluor 488, ex. 480/40 LP; Alexa Fluor 594, ex. 546/12; and Alexa Fluor 532, ex.535. Photos were taken using an AxioCam and AxioVision software (version 4.6; Carl Zeiss MicroImaging, Inc.). Each fluorochrome was imaged separately, and the resulting images were automatically pseudocolored and merged by the AxioVision software.

Statistical analysis. Statistical significance was calculated by the two-tailed t test and linear regression analysis. P < 0.05 was considered significant.

Online supplemental material. Fig. S1 shows that CD4+CD25+CD45RO+IL-7Rαhigh cells secrete inflammatory cytokines. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20062120/DC1.

The authors would like to thank the Lausanne and Geneva transplant coordinators and Christiane Rotzetter for their precious help, as well as all the patients who agreed to take part in this study. They also thank Véronique Noguet and Nicole ProdHom for introducing L Codami to the techniques of immunohistochemistry, as well as Solange Moll for advice in the immunostaining techniques. Finally, they thank Yannis Krempp for graphical support and suggesting ideas.

The Centre Hospitalier Universitaire Vaudois Transplantation Center is supported by the 2004–2007 Strategic Plan of the Hospices–Centre Hospitalier Universitaire Vaudois, and M. PASCUAL received a grant from the Leenards Foundation. The work of L. Vallotton is supported by a Swiss National Foundation grant (FN 323500-111275).

The authors have no conflicting financial interests.
