Thymic T cell lineage commitment is dependent on Notch1 (N1) receptor–mediated signaling. Although the physiological ligands that interact with N1 expressed on thymic precursors are currently unknown, in vitro culture systems point to Delta-like 1 (DL1) and DL4 as prime candidates. Using DL1- and DL4-lacZ reporter knock-in mice and novel monoclonal antibodies to DL1 and DL4, we show that DL4 is expressed on thymic epithelial cells (TECs), whereas DL1 is not detected. The function of DL4 was further explored in vivo by generating mice in which DL4 could be specifically inactivated in TECs or in hematopoietic progenitors. Although loss of DL4 in hematopoietic progenitors did not perturb thymus development, inactivation of DL4 in TECs led to a complete block in T cell development coupled with the ectopic appearance of immature B cells in the thymus. These immature B cells were phenotypically indistinguishable from those developing in the thymus of conditional N1 mutant mice. Collectively, our results demonstrate that DL4 is the essential and nonredundant N1 ligand responsible for T cell lineage commitment. Moreover, they strongly suggest that N1-expressing thymic progenitors interact with DL4-expressing TECs to suppress B lineage potential and to induce the first steps of intrathymic T cell development.

The thymus is continuously seeded by progenitors derived from hematopoietic stem cells, which reside in the BM. These progenitors migrate via the blood stream into the thymus, where they adopt a T cell fate, proliferate, and differentiate into mature functional T cells. This differentiation process is characterized by multiple developmental stages. The earliest thymic progenitors lack surface expression of CD4 and CD8 and are therefore referred to as double-negative (DN) thymocytes. They subsequently up-regulate both CD4 and CD8 coreceptors (double positive [DP]) before undergoing positive and negative selection, and maturing to CD4 and CD8 single-positive (SP) thymocytes that emigrate to the periphery. Immature DN thymocytes can be subdivided into four subpopulations according to the surface expression of CD117, CD44, and CD25. The most immature thymocyte progenitors (DN1) express CD117 and CD44 and are negative for CD25, followed by the DN2 population, which up-regulates CD25, and the DN3 cells, which down-regulate CD117 and CD44 before generating DN4 thymocytes lacking expression of all three markers (1, 2).

Over the last decade, many reports highlighted the importance of the evolutionarily conserved Notch cascade for the lymphoid system (3). Mammals possess 4 Notch receptors (N1–4), which are activated by two classes of
transmembrane bound ligands named Jagged 1 and 2, and Delta-like (DL) 1, 3, and 4. Notch signaling is initiated upon ligand receptor interaction, which results in the proteolytic release of the Notch intracellular cytoplasmic domain (NICD) of Notch receptors. The liberated NICD translocates to the nucleus and binds to the transcription factor RBP-J (also known as CSL), thereby converting it from a transcriptional repressor into an activator. Mastermind-like proteins are required for Notch signaling, as they bind to the NICD–RBP-J complex and recruit additional coactivators.

Multiple genetic loss- and gain-of-function experiments show that signaling mediated through the N1 receptor plays an important role for T cell lineage commitment and maturation within the thymus. Inducible inactivation of N1 in BM progenitors results in a block in T cell development and ectopic B cell development in the thymus, suggesting that N1 instructs an early thymic progenitor to adopt a T cell fate (4, 5). An identical phenotype is observed in mice in which the RBP-J gene was inactivated in BM progenitors (6), strongly indicating that T cell specification is mediated by N1–RBP-J–dependent signaling. Interference with Notch signaling by transgenic expression of modulators (such as Fringe, Delta, or Notch) or dominant-negative forms of transcriptional co-activators (mastermind-like) also blocks T cell development concomitant with B lymphopoiesis in the thymus (for review see reference 3). Reciprocal gain-of-function studies over-expressing NICD in BM progenitors result in ectopic T cell development at the expense of B cell development (3). Thus, both loss- and gain-of-function studies demonstrate that N1 is essential for T lineage commitment. In addition, N1–RBP-J signaling promotes the differentiation of pro–T cells into pre–T cells within the thymus by controlling rearrangement of the TCR β locus (7) through regulating chromatin accessibility (8), thereby assuring the successful generation of a pre-TCR complex, which is essential for thymocyte development.

Although N1 is unequivocally the key Notch receptor involved in T lineage commitment and thymic T cell maturation in vivo, the ligands that could be the physiological partners of N1 in these processes are still a matter of debate. The thymic epithelial microenvironment expresses all Notch ligands (mainly assessed by RT-PCR), except DL3, which is hardly found in this organ (9–12). However, both Jagged ligands can be excluded from playing an essential role, as Jagged2−/− and, more recently, Jagged1−/− mice have been shown to have normal T cell development (13, 14), thus implicating DL1 and/or DL4 ligands. Historically, DL1 has been favored as the potential N1 ligand in T cell fate specification, because DL1-expressing stromal cells can support the complete development of mature functional T cells from BM precursors in vitro (10). Moreover, when BM progenitors are co-cultured on stromal cells overexpressing DL1, B cell development is blocked (15). Surprisingly, in contrast with these promising data obtained in vitro, conditional inactivation of DL1 in thymocytes and/or thymic epithelial cells (TECs) does not inhibit T cell development (16). This discrepancy may be caused by the in vivo presence of DL4, which shares a high degree of homology with DL1. Data obtained in vitro support this hypothesis, because overexpression of DL4 in stromal cells can also direct T lymphopoiesis (16, 17). In addition, overexpression of DL4 in BM precursors transferred into γ-irradiated mice leads to ectopic T cell development in the BM as well as a severe defect in B cell development (17–19). Moreover, we recently described a hierarchy of Notch–Delta interactions showing that the avidity of DL4 to bind to immature thymocytes is much higher than that of DL1. DL4 binding is high from the DN1 to DN3 stages and declines in DN4 to become undetectable in subsequent DP and SP thymocytes. This binding pattern parallels the functional requirements of Notch signaling during thymocyte development (20, 21), suggesting that DL4 might play an important role during T cell development within the thymus.

In this report, we explore the function of DL4 within the thymus using a conditional loss-of-function approach. Our data show that Foxn1-Cre–mediated inactivation of DL4 within the thymic epithelium leads to a complete block in T cell development accompanied by ectopic B cell development within the thymus, which phenocopies mice with inducible inactivation of N1 in BM progenitors. Thus, DL4 is essential for T cell fate specification and thereby represents the physiological partner of N1 during this process.

RESULTS AND DISCUSSION
Because DL1– and DL4-expressing OP-9 stromal cells (10, 16, 17) or normal thymic stroma (22) can both support the complete development of mature functional T cells from BM precursors in vitro, it is conceivable that either or both of these proteins function as physiological ligands for the N1 receptor during thymic T cell lineage commitment. To gain further insight into the expression pattern of DL1 and DL4 in the thymus, we analyzed thymi of mice in which the lacZ gene was knocked into either the DL1 or DL4 locus (23, 24). LacZ staining on thymic sections derived from DL4lacZ/− mice was only positive for rare endothelial cells within the thymus, whereas DL4lacZ/+ mice exhibited a strong reticular expression pattern within the outer cortex (characteristic of epithelial cells) and a weaker more punctuated staining within the medulla of the thymus (Fig. 1A). This expression pattern was confirmed at the protein level using novel mAbs generated against the extracellular domains of DL1 and DL4. The specificity of the anti-DL1 and −DL4 mAbs was tested on DL1– and DL4-expressing OP-9 cells. Anti-DL1 mAbs bound specifically to DL1– but not to DL4-expressing OP-9 cells, whereas the anti-DL4 mAbs showed a reciprocal binding pattern (Fig. 1B).

These results indicate that both mAbs specifically bind to the corresponding Notch ligands and that they do not exhibit any cross-reactivity. These mAbs were then used to stain cell preparations enriched for TECs and analyzed by flow cytometry. TECs were identified as CD45− PanCytokeratin (PanCyt)+ (25) and were further subdivided into cortical TECs (cTECs) and medullary TECs (mTECs) based on BPI expression (26). Anti-DL1 mAbs did not stain cTECs or mTECs above background. In contrast anti-DL4 mAbs showed significant staining
Figure 1. DL4 but not DL1 expression is detected on TECs. (A) LacZ staining on thymic sections derived from DL1 and DL4 lacZ knock-in mice. mRNA expression of the DL1-driven lacZ gene is confined to blood vessels within the thymus, whereas DL4 drives expression preferentially within the cortical epithelium. The dashed lines indicate cortical–medullary boundaries. Bars, 100 μm. (B) Anti-DL1 and -DL4 antibodies specifically bind their corresponding ligands without exhibiting cross-reactivity; OP-9–DL1–EGFP (top) and OP-9–DL4–EGFP (bottom) were stained with isotype Ctrl (shaded), anti-DL1 (dashed line), or anti-DL4 antibodies (continuous line; dilution, 1:100). The analysis was performed on gated EGFP-positive cells, and representative histograms are shown. (C) Anti-DL1 and -DL4 antibody staining on TECs. Enriched TECs extracted from wild-type thymi were stained for BP1 (3C6), CD45, and isotype Ctrl, anti-DL1, or anti-DL4 antibodies, followed by intracellular staining for PanCyt (C11) and flow cytometric analysis. Total TECs were gated as PanCyt<sup>−</sup>CD45<sup>−</sup> (top left), and cTECs and mTECs were further defined as BP1<sup>−</sup> and BP1<sup>+</sup>, respectively (bottom left); isotype Ctrl (shaded), anti-DL1 (dashed line; top right), and anti-DL4 (continuous line; bottom right) are shown. Percentages of DL4<sup>+</sup> TECs represent the mean ± SD of five mice. (D) DL1 and DL4 are not detectably expressed on thymocytes. Left) A representative flow cytometric analysis of CD4 versus CD8 of wild-type thymocytes. (right) DL1 and DL4 expression are shown as representative histograms (shaded, isotype Ctrl; dashed line, DL1; continuous line, DL4) after gating on the indicated thymic subpopulations: DN (Lin<sup>−</sup>, CD4<sup>+</sup>, CD8<sup>−</sup>), DP (Lin<sup>−</sup>, CD4<sup>+</sup>, CD8<sup>+</sup>), CD4<sup>SP</sup> (Lin<sup>−</sup>, CD4<sup>+</sup>, CD8<sup>−</sup>), and CD8<sup>SP</sup> (Lin<sup>−</sup>, CD4<sup>−</sup>, CD8<sup>+</sup>) thymocytes. Percentages of individual thymic subpopulations are indicated within the plots. Data are representative of three independent experiments.
of TECs, with brighter staining for cortical- (BP1+) versus medullary- (BP1−) derived populations (Fig. 1 C). Analysis of thymocyte subpopulations for the expression of DL1 and DL4 with these mAbs was negative (Fig. 1 D). These expression data are in general agreement with previous studies (18, 27, 28), with the notable exception of one report in which TECs were broadly stained by a commercial polyclonal antibody against DL1 (12). The specificity of this polyclonal reagent has already been challenged by others (29).

In conclusion, the thymic expression pattern of DL1 and DL4 revealed by our novel mAbs confirms the results obtained with the lacZ knock-in mice, strongly suggesting that DL4 might be the physiological ligand expressed by TECs that interacts with N1-expressing T cell precursors to specify the T cell lineage.

Studying the role of DL4 in hematopoiesis and, more specifically, during T lineage commitment by a conventional loss-of-function approach is hampered by the fact that DL4 gene-targeted mice are embryonic lethal (24, 30). We therefore generated conditional gene-targeted mice for DL4. These mice carry loxP sites flanking the first three coding exons of the DL4 gene (DL4<sup>lox/lox</sup>). Because the gene expression and antibody studies suggested that DL4 expression in TECs might be critical for T cell lineage commitment, we crossed the DL4<sup>lox/lox</sup> (Ctrl) mice to knock-in mice expressing the Cre recombinase under the control of the Foxn1 gene (31), which is highly expressed in TECs, to generate DL4<sup>lox/lox</sup>Foxn1-Cre (DL4<sup>Foxn1<sup>-</sup></sup>) mice (Fig. 2 A). Staining of DL4<sup>Foxn1<sup>-</sup></sup> TECs with anti-DL4 and -DL1 mAbs confirmed the complete loss of DL4 protein in the gene-targeted mice compared with Ctrl animals (Fig. 2 B). Interestingly, DL1 expression on TECs derived from DL4<sup>Foxn1<sup>-</sup></sup> mice was not detectable, indicating that there is no functional compensation by DL1 as a consequence of loss of DL4 (Fig. 2 B).

Side-by-side analysis of littermate thymi derived from Ctrl and DL4<sup>Foxn1<sup>-</sup></sup> mice revealed a 14-fold decrease in absolute thymocyte numbers in DL4<sup>Foxn1<sup>-</sup></sup> compared with Ctrl mice (Fig. 3 A). Flow cytometric analysis of CD4 and CD8 expression on thymocytes derived from DL4<sup>Foxn1<sup>-</sup></sup> mice shows nearly complete loss (<1%) of the CD4SP, the CD8SP, and the DP thymocyte subsets, whereas all of the major subsets are present in the expected frequency in Ctrl mice. DL4<sup>Foxn1<sup>-</sup></sup>-derived thymi were almost exclusively populated with cells falling into the DN gate (Fig. 3 A). In absolute numbers, DP, CD4SP, and CD8SP subsets were reduced by 180–3,000-fold in DL4<sup>Foxn1<sup>-</sup></sup> mice, whereas DN cells were slightly increased (twofold). Whether the small residual population of T lineage cells in the thymus of DL4<sup>Foxn1<sup>-</sup></sup> mice results from a failure to

Figure 2. Specific targeting of the DL4 gene in TECs by the Foxn1-Cre recombinase. (A) A schematic representation of the genomic organization of the DL4<sup>lox/lox</sup> locus is shown. Exons 1–3 are flanked by loxP sequences (black triangles). DL4<sup>lox/lox</sup> mice were crossed to mice in which the Cre recombinase was knocked into the Foxn1 locus (Foxn1-Cre) to obtain DL4<sup>lox/lox</sup>Foxn1-Cre mice (DL4<sup>Foxn1<sup>-</sup></sup>). (B) Histograms of total TECs (PanCyt+CD45<sup>+</sup>), cTECs (PanCyt+CD45<sup>+</sup>BP1<sup>+</sup>), and mTECs (PanCyt+CD45<sup>+</sup>BP1<sup>-</sup>) from Ctrl (DL4<sup>lox/lox</sup>) or DL4<sup>Foxn1<sup>-</sup></sup> mice stained for DL1 (shaded) and DL4 (continuous lines). DL1 staining was indistinguishable from Ctrl isotype staining (not depicted). Data are representative of five Ctrl and three DL4<sup>Foxn1<sup>-</sup></sup> mice aged 2–3 wk from three independent experiments. Percentages of cells positively staining for DL4 are indicated in the histograms.
delete DL4 efficiently in a subset of TECs (which stain below the threshold of detection with our anti-DL4 mAb) or, alternatively, represents a minor pathway of DL4-independent (and hence, presumably Notch-independent) T cell development remains to be investigated.

Further analysis of the DN thymic compartment of DL4Foxn1 mice for CD44 and CD25 expression reveals the presence of only CD44+CD25− DN1 cells, whereas all immature thymocyte subsets (DN1–4) were present in normal numbers in Ctrl animals (Fig. 3 B). Thus, the thymic phenotype of DL4Foxn1 mice is very similar to the one previously published for Notch1loxloxCre (N1ΔΔc) mice (4, 5). In the case of N1ΔΔc mice, accumulating DN1 cells in the thymus were found to be ectopically developing B cells (4, 5). Similarly, essentially all CD44+CD25− DN cells in DL4Foxn1 mice expressed B220, whereas only a small fraction of DN1 cells in Ctrl thymi were B220+ (Fig. 3 C). To examine this phenotypic similarity in greater detail, we studied side-by-side B cells within the thymi of 2-wk-old Ctrl, DL4Foxn1, and N1ΔΔc mice 2 wk after N1 inactivation and compared them with BM B cells.

A small number of thymic B cells are present in Ctrl mice, and the majority have a mature IgM+B220+ phenotype. In contrast, a much larger population of B cells was found in DL4Foxn1 and N1ΔΔc mice, and these B cells express heterogeneous levels of IgM and B220. Moreover, DL4Foxn1 and N1ΔΔc B cells also express CD93 and BP1, which are typical markers for immature B cells, normally only present in the BM (Fig. 4 A). All B220+IgM− cells within the thymi of DL4Foxn1 and N1ΔΔc mice were CD19+, confirming that these are indeed immature B cells (unpublished data). In absolute numbers, immature thymic B cells were increased 340- and 30-fold over Ctrl values in DL4Foxn1 and N1ΔΔc mice, respectively (Fig. 4 B). In conclusion, the immature B cell phenotype observed in the thymi of N1ΔΔc mice is largely recapitulated in DL4Foxn1 mice, strongly suggesting that DL4 is the natural ligand for N1 during thymic T cell lineage commitment.

Figure 3. Complete block in T cell development and accumulation of thymic B cells in DL4Foxn1 mice. (A) Representative flow cytometric analysis of thymocytes derived from Ctrl and DL4Foxn1 14-d-old mice. Total thymocytes were stained with anti-CD4 and -CD8 antibodies. Absolute cell numbers for total thymocytes and indicated subsets are shown as bar diagrams on a logarithmic scale. The bar diagrams represent mean values ± SD (n = 5 for Ctrl and 6 for DL4Foxn1). (B) Representative FACS analysis of CD4+CD8−lin− thymocytes stained with anti-CD44 and -CD25 antibodies. (C) Representative histograms of B220 staining gated on lin−CD44+CD25− cells. Data are representative of three independent experiments. Percentages of positively stained cells are indicated within the contour plots and histograms.
Although DL4\(^{\text{Foxn1}}\) and N1\(^{\text{Mx}}\) mice exhibit qualitatively similar thymic phenotypes, it is clear that enhancement of immature B cell development (Fig. 4 B) is more pronounced in the DL4\(^{\text{Foxn1}}\) background. This quantitative difference between DL4\(^{\text{Foxn1}}\) and N1\(^{\text{Mx}}\) mice most likely reflects the consequence of inactivation of the floxed DL4 and N1 genes using two different Cre systems. The Mx-Cre transgene inducibly inactivates floxed genes preferentially in hematopoietic cells in the BM (32). Thus, postnatal inactivation of N1 will generate N1-deficient BM progenitors that will have to compete with residual thymocytes for the availability of thymic niches, growth factors, and cytokines. In contrast, constitutive Foxn1-Cre-mediated DL4 gene inactivation in TECs occurs already during embryogenesis (31). Thus, the first wave of incoming lymphoid progenitors will encounter an empty DL4-deficient thymic epithelium. Although these precursors cannot be instructed toward the T cell lineage, they can develop into the B cell lineage and efficiently expand in the absence of competition, as all necessary cytokines and growth factors are abundantly present in the neonatal thymus.

Although Foxn1-Cre expression within the thymus should be restricted to TECs (31) and wild-type thymocytes do not stain detectably with anti-DL4 mAbs (Fig. 1 D), it remains formally possible that rare DL4-expressing hematopoietic cells might be involved in T cell lineage commitment in the thymus. In this scenario, loss of DL4 expression on these cells could theoretically contribute to the generation of immature B cells in the DL4\(^{\text{Mx}}\) thymus. To exclude this possibility, we generated DL4\(^{\text{lox/loxMx-Cre}}\) (DL4\(^{\text{Mx}}\)) mice to inducibly inactivate DL4 in BM progenitors. Because the Mx-Cre transgene is also active to some extent in TECs (16), BM from DL4\(^{\text{Mx}}\) or Ctrl mice (both CD45.2\(^{+}\)) was transplanted into CD45.1\(^{+}\) wild-type hosts to critically evaluate whether DL4\(^{\text{Mx}}\) hematopoietic cells could contribute to the phenotype. Ctrl and DL4\(^{\text{Mx}}\) BM chimeras were analyzed 8 wk after transplantation. The reconstitution efficiency of CD45.2\(^{+}\) cells for
both Ctrl and DL4<sup>loxP<sub>Mx</sub></sup> chimeras was >95%. A portion of the BM cells of the corresponding BM chimeras was analyzed by Southern blot analysis to ensure that reconstitution was not caused by rare cells that might have escaped deletion of the DL4 locus (Fig. 5 E). As expected, Ctrl and DL4<sup>loxP<sub>Mx</sub></sup> BM progenitors generated all major blood lineages in the BM and spleen (unpublished data). More importantly, all major mature and immature thymocyte subsets were generated normally from Ctrl and DL4<sup>loxP<sub>Mx</sub></sup> BM progenitors (Fig. 5, A and B), and only very small numbers of immature B cells were found in the thymus (Fig. 5, C and D). These data exclude a significant role for putative DL4-expressing hematopoietic cells in thymic T cell lineage commitment.

Collectively, we have shown that DL4 is expressed by TECs, whereas DL1 is not detectable. Moreover, DL4<sup>loxP<sub>FRT</sub></sup> mice exhibit a loss of DL4 expression in TECs, which correlates with a complete block in T cell development and the accumulation of immature B cells within the thymus. DL4 deficiency within hematopoietic progenitors seems not to contribute to this phenotype, as assessed by BM chimeras, suggesting that the loss of DL4 on TECs is causative. A similar accumulation of immature thymic B cells is found in mice in which the N1 receptor is inactivated in hematopoietic progenitors. Collectively, these data demonstrate that DL4 expression on TECs is essential for thymic T cell development. Furthermore, they strongly suggest that N1-expressing T cell progenitors only commit to the T cell lineage after entry into the thymus.

Although in vitro DL1 and DL4 are functionally redundant in their ability to promote T cell development from BM precursors when expressed on OP9 cells, in vivo DL1 and DL4 mediate nonredundant functions within the hematopoietic system by binding to specific Notch receptors. Our data demonstrate that DL4 expression on TECs is essential for thymic T cell development. Furthermore, they strongly suggest that N1-expressing T cell progenitors only commit to the T cell lineage after entry into the thymus.

MATERIALS AND METHODS

Mice: generation of DL4 gene-targeted floxed mice. We generated the conditional DL4 loss-of-function mutant mice by flanking the first three exons of the DL4 allele with two loxP sites. Mouse DL4 genomic clones were isolated from a 129/Sv genomic library. One loxP site was inserted into the 5′ untranslated region in the Xhol restriction site, 75 bp downstream of the transcription initiation site. The other loxP site was inserted into the 5′ untranslated region in the Xhol restriction site, 75 bp downstream of the transcription initiation site. The other loxP site, together with the flippase recognition target (FRT) site–flanked PGK-neomycin selection cassette, was inserted in the EcoRI restriction site of intron 3. Upon Cre-mediated recombination, the translation initiation site and the coding sequence for the first 132 amino acids of the protein were removed, creating a null allele. Electroporation and selection of embryonic stem (ES) cells (R1) was performed using standard protocols. Homologous recombination of the targeted DL4.

Figure 5. Normal T cell development and absence of immature thymic B cells in BM chimeras reconstituted with DL4<sup>loxP<sub>Mx</sub></sup> BM. Ctrl or DL4<sup>loxP<sub>Mx</sub></sup> CD45.2<sup>+</sup> BM was transplanted into lethally irradiated CD45.1<sup>+</sup> hosts and analyzed 8 wk after reconstitution. The reconstitution efficiency for both Ctrl and DL4<sup>loxP<sub>Mx</sub></sup> BM chimeras was >95% (not depicted). (A) Representative flow cytometric analysis of CD45.2<sup>+</sup> thymocytes stained with anti-CD4 and -CD8. (B) CD45.2<sup>+</sup> lineage-negative DN thymocytes were analyzed for the expression of CD44 and CD25. (C and D) Lineage-negative thymocytes were analyzed for the presence of B cells expressing B220 and IgM, or BP1 and CD93. Data in A–D are representative of three individual chimeras per group with virtually identical results, and relative percentages are indicated in the contour plots. Two independent experiments were performed. (E) Southern blot analysis of ScaI-digested genomic DNA derived from BM cells of Ctrl and DL4<sup>loxP<sub>Mx</sub></sup> chimeras showing the floxed alleles in Ctrl chimeras and the completely deleted DL4 locus in DL4<sup>loxP<sub>Mx</sub></sup> chimeras. The targeting strategy and size of the restriction fragments are as described in Fig. 2 A.
locus in ES cells was confirmed first by PCR and then by Scal restriction dig- 
gest of the genomic tail DNA and Southern blotting. A 400-bp Apal-Apal 
genomic fragment localized upstream of the 5' arm of the targeting vector 
was used as a probe (Fig. 2 A). Blastoyct injection of the targeted ES cells 
was performed according to standard protocols. To remove the FRT site– 
flanked PGK-neomycin selection cassette, germline chimeras were crossed with 
ACTB-Flpe mice (35) in a pure C57BL6 background. DL4 homozygous 
flxed mice were obtained in the expected Mendelian ratio, suggesting normal 
expression of a functional DL4 protein from the modiﬁed allele. Homozy- 
gous DL4/dm mice were bred to Mx-Cre mice (32) and to Foxn1-Cre mice (31) to generate DL4/dm/Mx-Cre−/− and DL4/dm/Foxn1-Cre−/− mice, re- 
spectively. These mice were intercrossed to generate DL4/dm/Mx-Cre+/− (DL4/dm+/+) mice and were subsequently backcrossed for at least ﬁve generations into C57BL6 mice. Mice were gen- 
typed for homozygosity of the loxP sites and for the presence of the Mx-Cre 
or Foxn1-Cre transgene by PCR.

Conditional gene-targeted N1 mice were previously described (4). B6.SJL-Ptprc−/− (CD45.1+) mice were originally purchased from the Jackson 
Laboratory. CD45.1+ recipient mice were used as BM recipients for the chi- 
meras described in the following section. This study has been reviewed and 
approved by the Service Vétérinaire Cantonal of Etat de Vaud.

BM chimeras. BM chimeras were generated using T cell–depleted BM 
cells from polyI-polyC (pI-pC; Invivogen) injected into OP-9–DL4–EGFP; (Fig. 1 B). 
Details of the immunization and screening will be presented in a future 
paper (unpublished data). Purifed mAbs were biotinylated in our laboratory 
according to standard protocols. Alexa Fluor protein labeling kits (Invitrogen). Intracellular staining of TECs was 
performed with a PanCyt mAb (C11) from Sigma-Aldrich.

Rat mAbs were generated against the extracellular domains of DL1 and 
DL4. Details of the immunization and screening will be presented in a future 
(unfinished data). Purifed mAbs were biotinylated in our laboratory 
according to standard protocols and revealed with streptavidin–PE. Both 
mAbs were assayed for specicity on OP-9 stromal cells engineered to ex- 
press DL1 or DL4 combined with enhanced GFP (OP-9–DL1–EGFP or 
OP-9–DL4–EGFP; Fig. 1 B).
