Abbreviations used: Aβ, amyloid β-protein; AD, Alzheimer’s disease; APP, β-amyloid precursor protein (APP) after β- and γ-secretase cleavage. The molecular mechanism underlying the pathogenesis of AD is not yet well defined, and there has been no effective treatment for AD. Valproic acid (VPA) is one of the most widely used anticonvulsant and mood-stabilizing agents for treating epilepsy and bipolar disorder. We found that VPA decreased Aβ production by inhibiting GSK-3β-mediated γ-secretase cleavage of APP both in vitro and in vivo. VPA treatment significantly reduced neuritic plaque formation and improved memory deficits in transgenic AD model mice. We also found that early application of VPA was important for alleviating memory deficits of AD model mice. Our study suggests that VPA may be beneficial in the prevention and treatment of AD.

Alzheimer’s disease (AD) is the most common neurodegenerative disorder leading to dementia. Neuritic plaques, neurofibrillary tangles, and neuronal loss represent the main histological hallmarks observed in AD brains. Amyloid β-protein (Aβ), the central component of senile plaques, is produced from sequential endoproteolytic cleavages of the type 1 transmembrane glycoprotein β-amyloid precursor protein (APP) by β- and γ-secretase (1). β-Site APP cleaving enzyme 1 (BACE1) is the β-secretase in vivo (2–6). γ-Secretase is an atypical multimeric membrane-protein aspartic protease composed of at least four subunits: presenilin (PS1 or PS2), nicastrin (Nct), APH-1 (APH-1aL, APH-1aS, or APH-1b), and PEN-2 (7–11). More recently, two additional proteins, CD147 and TMP21, were found to be closely associated with the γ-secretase complex (12, 13). The components of the γ-secretase complex are tightly regulated with each other, and PS1 is generally believed to be its catalytic core (14, 15). Another important substrate of γ-secretase is Notch, whose intracellular domain (NICD) is released upon γ-secretase cleavage and translocates to the nucleus, where it can activate transcription of downstream target genes (8, 10). In addition to its role in Notch signaling and APP processing, γ-secretase is also involved in regulating intramembrane proteolysis of many other type I integral membrane proteins, such as Jagged, Delta, E-cadherin, ErbB-4, Nectin-1, CD44, and LRP (16–22). Missense mutations in the PS1 and PS2 genes are major causes of early-onset familial AD (23–25). Although the underlying mechanism of AD neurodegeneration is currently unclear, Aβ accumulation appears to play a critical role in AD pathogenesis.

Valproic acid (VPA) is one of four first-line antiepileptic drugs being increasingly used in the treatment of bipolar disorder. Like other anticonvulsants, VPA inhibits sodium, potassium, and calcium channel functions. Although its direct in vivo target has yet to be definitively identified (26), VPA may enhance γ-aminobutyric acid transmission (27). VPA has been found to activate extracellular signal-regulated kinase, a protein kinase known to regulate AP-1 function, and mediate neurotrophic responses (28). VPA treatment could lead to a change in glycogen synthase kinase (GSK-3) and histone deacetylase (HDAC) activity (29). Furthermore, VPA, like lithium, regulates the Wnt signaling pathway by increasing β-catenin expression (30). Increased β-catenin expression is also seen after treatment with the chemically unrelated HDAC inhibitor trichostatin A. This mechanism may explain some effects of VPA on gene expression and neurodevelopment (31). It has been shown that increased histone acetylation by HDAC inhibitors facilitates synaptogenesis and improves learning and memory, suggesting that inhibition of HDAC may be a suitable therapeutic avenue for neurodegenerative diseases (32).

In this study, we examined the effects of VPA on AD neuropathology and behavioral deficits and identified its underlying mechanism. We found that VPA inhibited GSK-3β-mediated γ-secretase cleavage of APP both in vitro and in vivo. Furthermore, such inhibition decreased Aβ production and neuritic plaque formation, as well as alleviated the memory deficits in AD transgenic model mice. Our data suggest that VPA is effective for antiamyloid therapy in the prevention and treatment of AD.

RESULTS

VPA inhibits Aβ deposition and neuritic plaque formation in AD transgenic mice

To assess the effect of VPA treatment on AD neuropathology, APP23 transgenic mice, which are an AD mouse model, were subjected to VPA treatment. APP23 mice carry the human Swedish mutant APP751 transgene driven by the neuronal-specific Thy1.2 promoter (Fig. S1, available at http://www.jem.org/cgi/content/full/jem.20081588/DC1). APP23 mice develop amyloid plaques in the neocortex and hippocampus as early as 6 mo (33). APP23 mice were treated with 30 mg/kg VPA at 7 mo of age, whereas age-matched control APP23 mice received vehicle solution. To investigate whether VPA treatment could result in neuropathological changes in vivo, VPA-treated and control mice were killed after treatment and behavioral tests. 4G8 immunostaining and thioflavin S staining were used to detect Aβ-containing neuritic plaques in the brain (Fig. 1, A and B). Neuritic plaque formation was significantly decreased in APP23 mice treated with VPA (Fig. 1 A, b), relative to controls (Fig. 1 A, a). Quantification showed that overall VPA treatment reduced plaque number by ~4-fold (3.5 ± 0.79 vs. 14.95 ± 2.09 per slice; P < 0.0001; Fig. 1 D). The effects were similar among mice killed either immediately, 1 mo, or 2 mo after treatment and behavioral testing (0.75 ± 0.48 vs. 5.50 ± 1.32, P < 0.001; 2.33 ± 0.50 vs. 10.33 ± 1.26, P < 0.001; and 5.30 ± 1.33 vs. 21.5 ± 0.276, P < 0.001, respectively; Fig. S2). APP23 mice were also treated with VPA at 9 mo of age. Significantly more neuritic plaques were formed in the mice at 9 mo compared with 7 mo of age; however, VPA treatment starting at the age of 9 mo could also significantly reduce neuritic plaque formation (Fig. 1 A, c and d). The number of plaques in VPA-treated and control mice were 11.09 ± 0.92 and 25.60 ± 3.50, respectively (P < 0.005; Fig. 1 E). The area of plaques was also significantly reduced in VPA-treated mice compared with control by 43.10 ± 11.13% for the 7-mo-old group (P < 0.01) and by 59.66 ± 5.44% for the 9-mo-old group (P < 0.05). In addition to reducing neuritic plaque formation, VPA treatment also significantly increased microtubule-associated protein (MAP)-2 immunoreactivity (Fig. 1 C), which indicated a protective effect on dendritic damages and promoting neurite outgrowth in the transgenic mice. Similar results were obtained with silver staining (unpublished data).

To further confirm VPA’s effect on AD pathogenesis, APP23 transgenic mice were crossed with PS45 transgenic mice to generate APP23/PS45 double-transgenic mice. PS45 mice have an overexpression of the human familial AD-associated G384A mutant presenilin-1. The double-transgenic mice developed detectable neuritic plaques in the neocortex and hippocampus as early as 1 mo of age. Double-transgenic mice were treated with 30 mg/kg VPA at 6 wk of age for 4 wk. VPA treatment markedly inhibited neuritic plaque formation (Fig. 1 A, f and d) and significantly reduced plaque numbers from 14.84 ± 1.67 to 2.862 ± 0.65 (P < 0.0001; Fig. 1 F). Thioflavin S staining also confirmed VPA-induced reduction of Aβ-containing neuritic plaque formation in vivo.

VPA treatment significantly improves memory deficits in AD model mice

To investigate whether VPA treatment affects learning and memory in AD pathogenesis, behavioral tests were performed after APP23 mice received 1 mo of VPA treatment starting at the age of 7 mo. The Morris water maze was used to determine the effect of VPA on spatial memory. In the visible platform tests, VPA-treated and control APP23 mice had similar escape latency (53.190 ± 1.56 and 49.75 ± 2.47 s; P > 0.05; Fig. 2 A) and path length (7.03 ± 1.33 and 6.78 ± 1.60 s; P > 0.05; Fig. 2 B), which indicated that VPA treatment did not affect food and water consumption of the mice, and no significant weight changes were observed between the treatment and control groups (unpublished data). These data clearly demonstrate that VPA inhibits Aβ neuritic plaque formation in vivo.
swim significantly shorter distances to reach the platform (3.88 ± 0.91 and 2.68 ± 1.02 m) compared with control mice (6.03 ± 0.94 and 5.37 ± 1.38 m) on the third and fourth day (P < 0.01; Fig. 2 D). In the probe trial on the last day of testing, the platform was removed. VPA treatment significantly improved the AD mouse’s spatial memory. The number of times the

**Figure 1.** VPA treatment significantly reduces neuritic plaque formation in AD transgenic mice. (A) APP23 mice at the age of 7 or 9 mo and APP23/PS45 double-transgenic mice at the age of 6 wk were treated with 30 mg/kg VPA for 4 wk, whereas age-matched control APP23 mice received the vehicle solution. The mice were killed after behavioral tests and the brains were dissected, fixed, and sectioned. Neuritic plaques were detected using an Aβ-specific monoclonal antibody 4G8 and the DAB method. The plaques were visualized by microscopy with 40X magnification. The number of neuritic plaques was significantly reduced in VPA-treated mice compared with controls. b, d, and f show the representative brain section of the 7-mo APP23 age group, 9-mo APP23 age group, and APP23/PS45 mice treated with VPA, and a, c, and e show their controls, respectively. Black arrows point to plaques. (B) Neuritic plaques were further confirmed using thioflavin S fluorescent staining and visualized by microscopy at 40X magnification. There were less neuritic plaques in VPA-treated mice (b and d) compared with age-matched control mice (a and c). a and b show brain sections of APP23 mice, and c and d show the brain sections of APP23/PS45 mice. White arrows point to green fluorescent neuritic plaques. (C) The brain sections of APP23 were also stained with MAP-2 antibody. VPA treatment significantly increased the number of MAP-2–positive neurites. Bars: (A and B) 400 μm; (C) 200 μm. (D) Quantification of neuritic plaques in APP23 mice with treatment starting at the age of 7 mo, the number represents mean ± SEM. n = 30 mice each. * P < 0.0001 by Student’s t test. (E) Quantification of neuritic plaques in APP23 mice with treatment starting at the age of 9 mo, the number represents mean ± SEM. n = 12 mice each. * P < 0.005 by Student’s t test. (F) Quantification of neuritic plaques in APP23/PS45 mice with treatment starting at the age of 6 wk, the number represents mean ± SEM. n = 25 mice for control and 29 mice for VPA. * P < 0.0001 by Student’s t test.
mice traveled into the third quadrant, where the hidden platform was previously placed, was significantly greater with VPA treatment compared with control (9.56 ± 2.62 and 4.18 ± 1.06; P < 0.005; Fig. 2E). These data indicate that VPA treatment significantly improves the memory deficits seen in APP23 mice. Because VPA treatment stopped a day before and there was no treatment during the behavioral testing, the effect of VPA on the behavioral performance in the mice was not just acute, but also long lasting.

Behavioral tests were also performed on the older APP23 mice administered with VPA at the age of 9 mo to assess their cognitive function. Despite a significant reduction in plaque formation, there were no significant differences in the escape latency and path length in the hidden platform trial of the Morris water maze test between the treatment and control groups (P > 0.05). Although VPA treatment only slightly improved performance in the hidden platform tests in the APP23/PS45 double-transgenic mice, VPA treatment significantly improved performance in the probe trial (7.13 ± 0.70 and 3.43 ± 1.13; P < 0.05).

Behavioral tests were also performed on the older APP23 mice administered with VPA at the age of 9 mo to assess their cognitive function. Figure 2. VPA improves memory deficits in AD transgenic mice. A Morris water maze test consists of 1 d of visible platform tests and 4 d of hidden platform tests, plus a probe trial 24 h after the last hidden platform test. Animal movement was tracked and recorded by HVS 2020 Plus image analyzer. The 7-mo APP23 age group mice were tested after 1 mo of daily VPA (n = 30 mice) or vehicle solution (n = 30 mice) injections. (A) During the first day of visible platform tests, the VPA-treated and control APP23 mice exhibited a similar latency to escape onto the visible platform. P > 0.05 by Student’s t test. (B) The VPA-treated and control APP23 mice had similar swimming distances before escaping onto the visible platform. P > 0.05 by Student’s t test. (C) In hidden platform tests, mice were trained with 6 trials per day for 4 d. VPA-treated APP23 mice showed a shorter latency to escape onto the visible platform on the third and fourth day. P < 0.001 by ANOVA. (D) The VPA-treated APP23 mice had a shorter swimming length before escaping onto the hidden platform on the third and fourth day. P < 0.01 by ANOVA. (E) In the probe trial on the sixth day, the VPA-treated APP23 mice traveled into the third quadrant, where the hidden platform was previously placed, significantly more times than controls. * P < 0.005 by Student’s t test.
VPA alters APP processing and inhibits Aβ production in vivo and in vitro

Our data clearly demonstrated that VPA treatment inhibited neuritic plaque formation and improved the memory deficits in the AD model mice. To investigate the underlying mechanism, we examined the effect of VPA on APP processing. The level of APP C-terminal fragments (CTFs) and Aβ in the mouse brain tissues was assayed by Western blot analysis (Fig. 3 A). VPA treatment significantly increased the levels of APP CTFs. The levels of β-secretase-generated C99 and α-secretase-generated C83 fragments were increased by 227.7 ± 36.8% in the brains of VPA-treated mice relative to controls (P < 0.05; Fig. 3 B). Furthermore, the production of Aβ was significantly inhibited by VPA, and the total Aβ level was decreased to 18.71 ± 6.24% in the brains of VPA-treated mice relative to controls (P < 0.05; Fig. 3 B). The Aβ ELISA assay was also performed to measure Aβ40 and Aβ42 levels in the transgenic brain tissues. The levels of Aβ40 and Aβ42 were reduced to 67.64 ± 2.89 and 34.53 ± 1.53% in VPA-treated mice relative to controls, respectively (P < 0.05). To further confirm VPA’s effect on Aβ production, we measured Aβ40 and Aβ42 levels in the conditioned media of cultured primary cortical and hippocampal neurons derived from neonatal APP23/PS45 double-transgenic mice. VPA markedly reduced Aβ generation, decreasing Aβ40 and Aβ42 levels to 48.86 ± 1.52 and 58.90 ± 3.43%, respectively, relative to controls (P < 0.005; Fig. 3, C and D). VPA treatment had no significant effect on APP and PS1 protein levels (Fig. 3, A and B). The increased C99 and C83 levels, together with the decreased Aβ production in the brains of the VPA-treated transgenic mice, indicate that VPA inhibits γ-secretase cleavage of APP proteins.

To examine the effect of VPA on APP processing in vitro, 20E2 and H99C1 cells were treated with VPA. Consistent with in vivo data from transgenic mouse models, VPA significantly increased APP C99 and C83 generation in 20E2 cells, which are a HEK293 stable cell line overexpressing the Swedish mutant APP (Fig. 3 E) (34), and the levels of total CTFs were increased by 140.58 ± 5.5, 138.3 ± 5.58, 176.7 ± 2.73, and 179.64 ± 4.10% with 0.5, 1.5, 5, and 10 mM of VPA treatment, respectively (P < 0.001; Fig. 3 F). To further confirm the inhibitory effect of VPA on γ-secretase cleavage of APP, H99C1 cell line was established to stably overexpress APP C99, a major β-secretase cleavage product of APP (Fig. S3, available at http://www.jem.org/cgi/content/full/jem.20081588/DC1). VPA treatment significantly increased the levels of APP CTFs, including C99, C89, and C83 (Fig. 3 G). The levels of total CTFs were increased by 200.59 ± 4.10, 244.09 ± 3.87, 354.36 ± 17.30, and 400.24 ± 17.63% with 0.5, 1.5, 5, and 10 mM of VPA treatment, respectively (P < 0.001; Fig. 3 H). These data clearly indicated that VPA inhibited γ-secretase processing of APP C99 protein.

VPA inhibits GSK-3β activity

Our data demonstrated that VPA significantly decreased Aβ production and neuritic plaque formation in AD transgenic mice, likely by regulating APP processing through inhibition of γ-secretase activity. To further investigate the underlying mechanism of VPA’s effect, we first examined its effect on APP, BACE1, and PS1 gene expression. Our data show that VPA treatment did not change the mRNA levels of these genes (Fig. 4, A–C). Previous studies suggested that GSK-3β regulated Aβ formation (35–37). GSK-3β activity is regulated by its phosphorylation at the serine 9 (S9) and tyrosine 216 sites (Y216). The S9 phosphorylation (pGSK-3βS9) inhibits GSK-3β activity, whereas the Y216 phosphorylation (pGSK-3βY216)...

Figure 4. VPA inhibits GSK-3β activity. Total RNA was isolated from N2a cells by TRI-Reagent (Sigma-Aldrich). A set of gene-specific primers were used to amplify APP (A), BACE1 (B), and PS1 (C) genes. β-Actin was used as an internal control. There was no difference in endogenous APP, PS1, or BACE1 mRNA levels between VPA-treated cells and controls. (D) Brain tissues from APP23/PS45 double-transgenic mice were subjected to Western blot analysis to determine the levels of total GSK-3β and phospho–GSK-3βS9. VPA increases phospho–GSK-3βS9 levels, but not total GSK-3β levels in the transgenic mice. (E) N2a cells were treated with 5 mM of VPA for 0, 6, 12, and 24 h and lysed in RIPA-doc buffer containing a series of serine and tyrosine phosphatase inhibitors. The cell lysates were subjected to Western blot analysis using a rabbit anti-phospho–GSK-3βS9 antibody. Kodak Image Analysis software was used to quantify protein level. n = 3, *P < 0.001 by ANOVA. (F) Total GSK-3β level was also measured. (G) Promoter assay. pTOPFLASH plasmid was cotransfected with pcDNA3-β-catenin and pcDNA3-Tcf expression plasmids into N2a cells. pCMV-Rluc was also cotransfected to normalize transfection efficiency. Luciferase assay was performed 48 h after transfection. Promoter activity was indicated by the luciferase activity. VPA increased β-catenin-Tcf mediated transcription activation. n = 4, *P < 0.005 by Student’s t test.
up-regulates GSK-3β activity. To examine whether GSK-3β mediated VPA’s effect on APP processing in AD transgenic model mice, brain tissues of the double-transgenic mice were subjected to Western blot analysis for total GSK-3β and phospho-GSK-3β levels. We found no differences in total GSK-3β protein levels between the VPA treatment and control mice groups; however, VPA treatment also significantly increased GSK-3β59 levels in vivo (Fig. 4 D). Consistent with the transgenic mouse data, VPA treatment in vitro also significantly facilitated the phosphorylation of GSK-3β at the S9 site. The level of phospho-GSK-3β59 in VPA-treated N2a cells increased to 147.87 ± 12.38 and 181.18 ± 16.55% after 12- and 24-h treatment (P < 0.001; Fig. 4 E), whereas VPA had little effect on total GSK-3β level in N2a cells (P > 0.05; Fig. 4 F). Further phosphorylation screening by the Kinetworks 1.3 KPPS Phospho-site Profiling revealed that pGSK-3β Y216 levels were markedly reduced by 37%. Collectively, these data suggest that VPA negatively regulates GSK-3β activity. To examine the effect of VPA on GSK-3β-mediated biological activity, we performed a β-catenin–Tcf reporter gene assay. Phosphorylated β-catenin by GSK-3β is rapidly degraded by the ubiquitin proteasome pathway, therefore inhibition of GSK-3 stabilizes β-catenin and activates downstream gene transcription. TOPFLASH, containing three copies of the optimal Tcf motif CCTTTGATC upstream of a minimal c-Fos promoter driving luciferase expression (38), were co-transfected with β-catenin and Tcf expression plasmids into N2a cells. VPA treatment significantly potentiated β-catenin-mediated transcriptional activation, resulting in higher promoter activity (138.80 ± 1.37%; P < 0.005; Fig. 4 G). The up-regulatory effect of VPA was abolished when the cells were transfected with mutant β-catenin cDNA. Collectively, our data indicate that regulation of APP processing and neuritic plaque formation by VPA may be mediated by its effect on the GSK-3β signaling pathway.

**DISCUSSION**

There has been no effective method for the treatment or prevention of AD. Inhibition of HDAC activity with pharmacological agents demonstrated limited levels of synaptogenesis and improved learning and memory (32). Preclinical studies suggested that inhibition of Aβ production by altering APP processing at the β- or γ-secretase site by lithium or nonsteroidal antiinflammatory drugs could potentially be avenues for AD drug development (30, 39, 40). Here, we show that VPA, an antiepileptic drug, can serve as a highly effective antiamyloid treatment in AD transgenic model mice. VPA can inhibit GSK-3β, resulting in increased β-catenin protein levels (41, 42). GSK-3β is a key component of the Wnt signaling pathway, controlling β-catenin levels and transcriptional responses required for development and cell growth. Consistent with previous reports, we found that VPA inhibited GSK-3β activity by altering its phosphorylation state. VPA was also found to inhibit HDAC activity (29), which could improve learning and memory (32). Previous reports showed that VPA treatment not only induced synapsin I clustering in developing axons but also increased axonal branching and formation of curved axons (43). We show that VPA not only inhibits neuritic plaque formation but also promotes neurite outgrowth in the transgenic mice.

There have been VPA clinical trials conducted on AD patients. Profenno et al. reported that doses of <1,000 mg/d of divalproex sodium could be tolerated by patients in a Safety and Tolerability trial of 20 outpatients with probable AD (44). In a clinical trial conducted on 14 moderate to severe institutionalized AD patients with a mean age of 85.6 yr that assessed VPA’s effect on agitation and aggression, VPA treatment was found to be ineffective for the management of agitation and aggression (45). These reports had little data that addressed VPA’s effect on AD pathogenesis, neuropathology, and cognitive impairments. Consistent with a previous work which showed that both lithium and VPA inhibited Aβ production in a Swedish mutant APP751 stable cell line and PDAPP (APPV717F) transgenic mice (37), we systematically demonstrated that in two different transgenic AD mouse models, VPA has significant beneficial effects on AD pathogenesis. VPA reduced γ-secretase cleavage of APP and Aβ production in vitro and in vivo, resulting in the prevention of AD-associated pathological outcomes. Furthermore, our data showed that early administration of VPA not only reduced neuritic plaque formation, but also rescued some memory deficits in AD transgenic mice. Meanwhile, we found that the inhibitory effect of VPA on neuritic plaque formation was present up to 2 mo after discontinuing administration of VPA, indicating VPA’s long lasting antiamyloid treatment potential for AD patients. However, when mice were treated with VPA at a later stage, when there was profound neuritic plaque formation, VPA could still reduce further neuritic plaque formation, albeit a lesser effect on improving memory deficits in the older mice. Our preclinical animal study indicated that VPA can have effects on neuropathology changes at early and late stages, but cognitive impairments can only be improved at an early stage intervention. These data suggest that VPA treatment should be applied at early stages of AD pathogenesis for effective improvement of pathological and cognitive impairments. This information may also provide insights for VPA clinical trial designs. Our animal study suggests that the VPA trial might not show beneficial results on late or severe AD patients, whereas it might show significant improvements in early or mild AD patients.

**MATERIALS AND METHODS**

**Transgenic mice and VPA treatment.** Animal experiment protocols were approved by The University of British Columbia Animal Care and Use committee. APP23 transgenic mice carry human APP715 cDNA with the Swedish double mutation at positions 670/671 (KM→NL) under control of the murine Thy-1.2 expression cassette (33). PS45 transgenic mice carry human presenilin-1 cDNA with the M146V mutation. The genotype of the mice was confirmed by PCR using DNA from tail tissues. Mice were approved by The University of British Columbia Animal Care and Use committee. APP23 transgenic mice carry human APP717F transgenic mice with a previous work which showed that both lithium and VPA inhibited Aβ production in a Swedish mutant APP751 stable cell line and PDAPP (APPV717F) transgenic mice (37), we systematically demonstrated that in two different transgenic AD mouse models, VPA has significant beneficial effects on AD pathogenesis. VPA reduced γ-secretase cleavage of APP and Aβ production in vitro and in vivo, resulting in the prevention of AD-associated pathological outcomes. Furthermore, our data showed that early administration of VPA not only reduced neuritic plaque formation, but also rescued some memory deficits in AD transgenic mice. Meanwhile, we found that the inhibitory effect of VPA on neuritic plaque formation was present up to 2 mo after discontinuing administration of VPA, indicating VPA’s long lasting antiamyloid treatment potential for AD patients. However, when mice were treated with VPA at a later stage, when there was profound neuritic plaque formation, VPA could still reduce further neuritic plaque formation, albeit a lesser effect on improving memory deficits in the older mice. Our preclinical animal study indicated that VPA can have effects on neuropathology changes at early and late stages, but cognitive impairments can only be improved at an early stage intervention. These data suggest that VPA treatment should be applied at early stages of AD pathogenesis for effective improvement of pathological and cognitive impairments. This information may also provide insights for VPA clinical trial designs. Our animal study suggests that the VPA trial might not show beneficial results on late or severe AD patients, whereas it might show significant improvements in early or mild AD patients.
Morris water maze. The water maze test was performed in a 1.5-m-diam pool. A 10-cm-diam platform was placed in the southeastern quadrant in the hidden trial. The procedure consisted of 1 d of visible platform tests and 4 d of hidden platform tests, plus a probe trial 24 h after the last hidden platform test. In the visible platform test, mice were tested for 5 contiguous trials, with an intertrial interval of 30 min. In the hidden platform tests, mice were trained for 6 trials, with an intertrial interval of 1 h. Tracking of animal movement was achieved with an HVS 2020 Plus image analyzer (HVS Image). The data were analyzed by two-way ANOVA.

Immunohistochemical staining. Mice were killed after behavioral testing, and one half of the brains were immediately homogenized for protein, RNA, or DNA extraction. The other half of the brains were fixed in freshly depolymerized 4% paraformaldehyde and sectioned with a Cryostat (Leica) to 30 μm thickness. Every sixth slice with the same reference position was mounted onto slides for staining. Immunocytochemical staining was performed on floating sections. The slices were immunostained with biotinylated monoclonal 4G8 antibody (Signet Laboratories) in 1:500 dilution. Plaques were visualized by the ABC and DAB method and counted under microscopy at 40× magnification. Plaques were quantitated, and the mean plaque count per slice was recorded for each mouse. The data were analyzed by two-way ANOVA. Thioflavin S staining of plaques was performed with 1% thioflavin S, and the green fluorescence–stained plaques were visualized using fluorescence microscopy. For MAP-2 staining, sections were immunostained with anti–MAP-2 (Signet Laboratories).

Cell culture, transfection, and luciferase assay. All cells were maintained at 37°C in an incubator containing 5% CO2. The 20E2 cell line is a Swedish mutant APP stable HEK cell line. Cells were transfected with plasmid DNA using Lipofectamine 2000 (Invitrogen). HEK293 cells were stably transfected with pZ-C99mycHis to generate the H99C1 cell line. H99C1 cells stably overexpress APP C99, a major β-secretase product of APP. The mycHis-tagged C99 protein in H99C1 cells can be detected by both anti-myc 9E10 antibody and anti-APP C-terminal antibody C20. For primary neuronal cultures, hippocampal and neocortical tissues were removed from newborn mice at postnatal day 1, and gently digested with trypsin (0.025% EDTA; Invitrogen). The cells were suspended in neurobasal medium supplemented with B27 (Invitrogen) and plated at a density of 2 × 105 cells per 35-mm plate coated with 0.01 mg/ml poly-d-lysine (Sigma-Aldrich). Tails from the newborn mice were used to isolate genomic DNA for genotyping. The primary cultures were maintained at 37°C in a humidified incubator containing 5% CO2. For the β-catenin–mediated transcriptional activation assay, pTOPFLASH plasmid was co-transfected with pcDNA3-β-catenin and pcDNA3–Tf expression plasmids into N2a cells. The Renilla (sea pansy) luciferase vector pCMV-Rluc was cotransfected to normalize transfection efficiency. Luciferase assay was performed 48 h after transfection with Dual–Luciferase Reporter Assay system (Promega), as previously described (2).

Immunoblotting. Brain tissue or cells were lysed in RIPA lysis buffer (1% Triton X-100, 1% sodium deoxycholate, 4% SDS, 0.15 M NaCl, and 0.05 M Tris-HCl, pH 7.2) supplemented with protease inhibitors (Complete; Roche). The lysates were resolved by 12% SDS-PAGE or 16% tricine-PAGE. Immunoblotting was performed as previously described (6). Rabbit anti-APP C-terminal polyclonal antibody C20 was used to detect APP and its CTF products. PS1 was detected by anti-PS1 N-terminal antibody 231, AB was immunoprecipitated from 50-μl aliquots of the tissue extract with 5 μl of primary antibody 4G8 plus protein G/A beads. Immunoprecipitates were subjected to 16% Tris-Tricine SDS-PAGE. The level of GSK-3β inhibition was assessed using a rabbit anti-phospho-GSK-3β antibody (Cell Signaling Technology, Inc.). The level of GSK-3β activation was assessed using a rabbit anti-phospho-GSK-3α/β antibody (BioSource International, Inc.). Total GSK-3β was determined using a pan-specific mouse anti–GSK-3α/β antibody (BioSource International, Inc.). Internal control β-actin was analyzed using monoclonal antibody AC-15 (Sigma-Aldrich).

RT-PCR. RNA was isolated from cells using TRI-Reagent (Sigma-Aldrich). PowerScript reverse transcription (Invitrogen) was used to synthesize the first-strand cDNA from an equal amount of the RNA sample following the manufacturer’s instruction. The newly synthesized cDNA templates were further amplified by Platinum Tag DNA polymerase (Invitrogen) in a 25-μl reaction. The following primers were used to specifically amplify APP, PS1, and BACE1 genes: BACE1, forward 5′-ACCGACGAAAGAGTCGGGAGGAG-3′ and reverse 5′-CACAATTGCTCTTGTACATAG-3′; APP, forward 5′-CGGAATCTCCGTGGTGTTCTTTGCGAAG-3′ and reverse 5′-CGGAATTCCGGTCTGACATCAAG-3′; PS1, forward 5′-GGATCCGCCACATGGTGTTGTGGTGAATATTGCGC-3′ and reverse 5′-CGGATCCGTCATATAAAAAATGTAGG-3′.

β-Actin was used as an internal control. The samples were analyzed on a 1.2% agarose gel.

Kinetwork KPPS 1.3 PhosphoSite analysis. N2A cells were treated with 5 mM of VPA for 12 h, followed by homogenizing in lysis buffer containing 0.5% Triton X-100, 2 mM EGTA, 5 mM EDTA, 20 mM MOPS, 200 mM sodium orthovanadate, 25 mM β-glycerophosphate, 20 mM sodium pyrophosphate, 30 mM sodium fluoride, 1 mM PMSF, and 1 complete mini protease inhibitor cocktail tablet (Roche Diagnostics). The samples were diluted in 4X SDS-sample buffer to give a final protein concentration of 1 μg/μl. The samples were then boiled and sent to Kinexus Bioinformatics Corp. for the Kinetworks KPPS 1.3 Phospho-Site multimonoblotting analyses. The KPPS 1.3 screen tracks the phosphorylation levels of >35 protein kinases and their substrates.

Aβ40/42 ELISA assay. Tissue extracts from transgenic mouse hippocampal and neocortical regions and conditioned cell culture media were collected. Protein inhibitors and AEBSF were added to prevent degradation of Aβ peptides. The concentration of Aβ40/42 was detected by β-amyloid 1–40 or 1–42 Colorimetric ELISA kit (BioSource International, Inc.) according to the manufacturer’s instructions.

Online supplemental material. Fig. S1 shows the genotyping of the AD transgenic mice. Fig. S2 shows the results of VPA’s effect on plaque formation in different age groups of APP23 mice. Fig. S3 shows the generation of human APP C99 stable cell line H99C1. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20081588/DC1.

We thank Michelle A. Christensen and Clement Kwok for their technical assistance. We also thank Kelley Bromley-Brits for helpful discussion.
