Production of type I interferon (IFN; IFN-αβ) increases host susceptibility to *Listeria monocytogenes*, whereas type II IFN (IFN-γ) activates macrophages to resist infection. We show that these opposing immunological effects of IFN-αβ and IFN-γ occur because of cross talk between the respective signaling pathways. We found that cultured macrophages infected with *L. monocytogenes* were refractory to IFN-γ treatment as a result of down-regulation of the IFN-γ receptor (IFNGR). The soluble factor responsible for these effects was identified as host IFN-αβ. Accordingly, macrophages and dendritic cells (DCs) showed reduced IFNGR1 expression and reduced responsiveness to IFN-γ during systemic infection of IFN-αβ-responsive mice. Furthermore, the increased resistance of mice lacking the IFN-αβ receptor (IFNAR−/−) to *L. monocytogenes* correlated with increased expression of IFN-γ–dependent activation markers by macrophages and DCs and was reversed by depletion of IFN-γ. Thus, IFN-αβ produced in response to bacterial infection and other stimuli antagonizes the host response to IFN-γ by down-regulating the IFNGR. Such cross talk permits prioritization of IFN-αβ–type immune responses and may contribute to the beneficial effects of IFN-β in treatment of inflammatory diseases such as multiple sclerosis.

The innate immune system is the first line of defense against pathogenic microbes. Phagocytic cells of the innate immune system, including macrophages, DCs, and neutrophils, patrol host tissues and rapidly engulf any bacteria or particulate microbes they encounter. Once engulfed, most organisms are killed. However, several pathogens, like *Listeria monocytogenes* and *Mycobacterium tuberculosis*, have evolved mechanisms for such probacterial effects of IFN-γ. Production of IFN-γ during infection is thought to be dependent on the detection of microbial products by a receptor present in the host cell cytosol (Leber et al., 2008). Although IFN-αβ elicits an antiviral state that promotes resistance to viral pathogens, IFN-αβ production increases the survival and replication of *L. monocytogenes*, *M. tuberculosis*, and several other pathogenic bacteria (Auerbuch et al., 2004; Carrero et al., 2004; Martin et al., 2009; Shahangian et al., 2009). Mechanisms for such probacterial effects of IFN-αβ have not been clearly defined, although previous work has correlated IFN-αβ production with increased cell death and differences in macrophage production of IL-10, IL-12, and TNF (Auerbuch et al., 2004; Carrero et al., 2004; O’Connell et al., 2004; O’Connell et al., 2004).

In contrast to IFN-αβ, IFN-γ is essential for host resistance to *L. monocytogenes* and other
intracellular pathogens (Buchmeier and Schreiber, 1985; Dalton et al., 1993). IFN-γ drives the differentiation of resting macrophages into an activated antimicrobial state (M1) that more efficiently restricts the growth of intracellular pathogens (Gordon, 2003). The effects of IFN-γ require its binding to the IFN-γ receptor (IFNGR) 1 subunit of a heterodimeric cell surface IFNGR. This binding triggers receptor clustering and activates a Janus kinase (JAK)–signal transducer and activator of transcription (STAT) signaling pathway that culminates in the binding of STAT1 to IFN-γ-activated sequence (GAS) elements in the DNA adjacent to IFN-γ-stimulated genes (Platanias, 2005). The expression of several IFN-γ-stimulated genes is up-regulated by IFN-γ, including those coding for class II MHC proteins (MHCIId) and the transcriptional activator of MHCIId, CIITA (Reith et al., 2005).

IFN-γ is produced in abundance by L. monocytogenes antigen-specific CD4+ and CD8+ T cells (Zenewicz and Shen, 2007; Harty and Badovinac, 2008). However, within the first few days of infection, the major sources of IFN-γ are NK cells of the innate immune system (Humann et al., 2007; Kang et al., 2008). This innate wave of IFN-γ production peaks around 24 h post infection (hpi) but fails to limit L. monocytogenes growth, which continues for the first 72 h after systemic infection. The continued bacterial growth in the face of innate IFN-γ suggests that the early production of IFN-γ is not sufficient to activate macrophage bactericidal activity.

In this paper, we present data indicating a mechanism by which L. monocytogenes prevents macrophage activation by innate IFN-γ. We find that both infected and bystander macrophages become refractory to stimulation by IFN-γ early after L. monocytogenes infection. This refractory state is the result of down-regulation of the IFNγR, which is induced by IFN-γ release from L. monocytogenes–infected cells. IFN-γ down-regulates cell surface IFNGR and attenuates macrophage activation during systemic L. monocytogenes infection only in mice expressing the receptor for type I IFN, IFN-αβ receptor (IFNAR). Mice lacking IFNAR expression consequently have increased expression of IFNγR and their reduced susceptibility to L. monocytogenes infection is dependent on IFN-γ. These studies reveal a mechanism by which IFN-αβ contributes to increased host susceptibility to bacterial infection and demonstrate a previously unappreciated mechanism of antagonistic cross talk between type I and II IFNs.

RESULTS AND DISCUSSION

L. monocytogenes infection inhibits macrophage responsiveness to IFN-γ

To test whether L. monocytogenes infection might suppress macrophage responses to IFN-γ, mouse BM-derived macrophages (BMMs) were subjected to a low multiplicity (multiplicity of infection [MOI] = 1) of WT L. monocytogenes (wt Lm) 2 h before treatment with IFN-γ. 20 h later, the infected and control BMMs were harvested and cell surface MHCII expression on live-gated cells was analyzed by flow cytometry (Fig. 1 A). Mock-infected BMM treated with IFN-γ showed 50–100× higher MHCII staining than BMM not treated with IFN-γ. However, nearly 95% of this IFN-γ–induced MHCII increase was blocked in BMM cultures that had been infected with wt Lm. These data suggest that the infection either specifically impaired expression of cell surface MHCII expression or more generally impaired macrophage responsiveness to IFN-γ.

Induction of MHCII transcription by IFN-γ requires the class II transactivator CIITA (Reith et al., 2005). To investigate the impact of wt Lm infection on IFN-γ–induced CIITA expression, we evaluated transcription of the CIITA-pIV isoform in control and infected BMM. IFN-γ–treatment increased transcription of CIITA-pIV in mock-infected BMM as judged by semiquantitative RT-PCR (Fig. 1 B). However, no induction of CIITA-pIV transcripts was seen in IFN-γ–treated BMM previously infected with wt Lm. Similarly, wt Lm infection prevented IFN-γ–induced luciferase reporter activity in RAW-CIITA-pIV reporter macrophages (Fig. 1 C), which were derived from RAW264.7 macrophages by stable transfection with a CIITA-pIV-luciferase reporter construct (Fortune et al., 2004). Thus, infection of macrophages with L. monocytogenes suppressed induction of both CIITA and cell surface MHCII.

To further discern whether the suppressive effects of L. monocytogenes were specific to CIITA, we developed an additional set of reporter cell lines. RAW264.7 cells were stably transfected with pHTS-GAS, a reporter construct containing four GAS elements upstream of a luciferase open reading frame. Reporter activity in the resulting RAW-GAS reporter cells was strongly induced by IFN-γ (Fig. 1 D) and inhibited by pretreatment with the STAT1–inhibitory anticancer agent fludarabine (not depicted; Frank et al., 1999). When RAW-GAS.6 or additional independently derived GAS reporter cell lines were infected with wt Lm before IFN-γ treatment, the induction of reporter gene activity was reduced by 50% (Fig. 1 D). Infection with wt Lm failed to suppress luciferase reporter activity driven by an hDHA promoter (unpublished data). In contrast to wt Lm, infection with a live mutant L. monocytogenes strain lacking expression of the LLO hemolysin (ΔHly Lm) had no impact on IFN-γ–dependent reporter gene activity (Fig. 1 D). Likewise, heat-killed wt Lm failed to significantly suppress RAW-GAS or RAW-CIITA-pIV cell reporter activity in response to IFN-γ (unpublished data). Finally, we evaluated levels of phospho (Y701) STAT1 after treatment of mock- or wt Lm–infected macrophages with recombinant IFN-γ (Fig. 1 E). The results indicated that IFN-γ treatment elicits significantly less pSTAT1 in macrophages infected for 6 h. Conversely, the response to IFN-γ was comparable to that of mock-infected cells at 2 hpi. Thus, prolonged infection of macrophages with viable L. monocytogenes that is capable of accessing the macrophage cytosol results in impaired responsiveness of these cells to IFN-γ.

Down-regulation of IFNGR expression accounts for the suppression of macrophage responsiveness to IFN-γ

To investigate the mechanism by which L. monocytogenes suppressed IFN-γ responsiveness, we evaluated the impact of...
wt Lm infection on expression of several macrophage genes important for responsiveness to IFN-γ. Total RNA was harvested from mock- and wt Lm–infected BMM and used for Affymetrix genechip analysis. The normalized expression of stat1 and jak2 increased by nearly 10-fold with wt Lm infection, whereas jak1 and ifngr2 expression were not affected (Fig. 2 A). In contrast, expression of ifngr1 was reduced by nearly sevenfold in the wt Lm–infected macrophages. These data indicate that wt Lm infection dramatically affects the expression of genes involved in responses to IFN-γ. In particular, the suppressed transcription of ifngr1 might be expected to interfere with cell surface IFNGR expression and, thus, macrophage responsiveness to IFN-γ.

We thus evaluated cell surface staining for IFNGR1 and IFNGR2 subunits. IFNGR1 detection was highly specific using a two-step staining procedure (Fig. S1). Our results indicated that surface expression of IFNGR1 was rapidly reduced in the wt Lm–infected cells, with a maximal reduction of

![Figure 1](jem.rupress.org)
The relative abundance of *ifngr1* and *ifngr2* transcripts was also evaluated in the mock- and wt Lm–infected BMM using quantitative RT-PCR. As predicted from the Affymetrix analysis, *ifngr1* transcription was significantly reduced within 4 hpi (Fig. 2 D). However, we failed to observe significant reductions in *ifngr2* transcription at any time point after the wt Lm infection. Given the contrasting behaviors of *ifngr2* transcripts and IFNGR2 surface staining, we hypothesize that the stability or cell surface localization of IFNGR2 is tightly linked to that of IFNGR1 at a post-transcriptional level. Indeed, BMM from B6.IFNGR1−/− mice failed to down-regulate IFNGR2 when infected with wt Lm (Fig. 2 E).

Together, these findings demonstrated that wt Lm infection triggers a rapid decrease in cell surface expression of both IFNGR1 and IFNGR2 subunits of the IFNGR, albeit through distinct mechanisms. The reduced availability of the

---

**Figure 2.** Suppression of macrophage responsiveness to IFN-γ after *L. monocytogenes* infection reflects rapid down-regulation of the IFNGR. (A) Total RNA was isolated from mock- and wt Lm–infected BMM at 10 hpi and hybridized to Affymetrix genechips. The mean fold change in normalized expression between mock- and wt Lm–infected BMM is shown for the indicated genes encoding proteins involved in IFN-γ signaling. (B) Mock-infected and wt Lm–infected BMMs were harvested at the indicated hpi, stained with antibodies to IFNGR1, IFNGR2, or CD11b, and analyzed by flow cytometry. Mean channel fluorescence intensities (MFI) from three infected samples per group were determined and normalized to the mean MFI of three mock-infected samples using the following formula: relative surface staining = (MFI Lm infected)/(MFI mock infected). (C) C57BL/6 BMMs were mock or wt Lm infected. One half of each sample was stained for cell surface IFNGR1 and the other half was permeabilized with saponin and stained for total cellular IFNGR1. Shown are representative histograms of IFNGR1 staining for each BMM population. MFIs are indicated in parentheses. (D) Real-time RT-PCR was used to quantify the relative transcript abundance of IFNGR1 and IFNGR2 at the indicated hpi. Samples were from the experiment in B. (E) B6.IFNGR1−/− BMMs were mock or wt Lm infected and analyzed for surface expression of IFNGR2 and CD11b. Shown is relative surface staining on wt Lm–infected cells. Error bars indicate SEM for three samples per condition. Asterisks indicate significant (P < 0.05) variations between Lm-infected and mock-infected samples. ns indicates P > 0.05. Horizontal lines represent the level of expression on uninfected cells. Experiments in B–E were repeated at least three times.
IFN-γ provides a mechanistic basis for the reduction in responsiveness of wt Lm–infected BMM to IFN-γ.

**IFN-γ is selectively down-regulated on antigen-presenting cell populations**

When C57BL/6 mice were infected i.v. with a sublethal dose of wt Lm (10,000 cfu), both splenic myeloid (CD11b+) and B lymphocyte (B220+CD19+) populations showed significant reductions in IFN-γR1 staining from 24 to at least 48 hpi (Fig. 3 A). IFN-γR1 staining remained low on CD11c+ gated DCs for at least 79 hpi (Fig. 3 A and see Fig. 5 A). Cell surface IFN-γR1 staining was also slightly, but not significantly, reduced on NK1.1+CD3+ NK cells (P > 0.05). However, no reduction was seen in IFN-γR1 staining on gated CD3+ T cells. These results indicated that down-regulation of IFN-γR1 selectively occurs on APC populations during the early stages of systemic infection with virulent *L. monocytogenes*. Furthermore, the results showed that IFN-γR1 was down-regulated on nearly all APCs in *L. monocytogenes*–infected mice (Fig. 3 A), despite the fact that only a fraction of APCs are infected with live bacteria at the infection dose used (10^4). We thus hypothesized that a soluble factor released from *L. monocytogenes*–infected cells was responsible for IFN-γR1 down-regulation.

A soluble factor released from infected cells mediates IFN-γ down-regulation and suppressed responses to IFN-γ

As a first step to directly evaluate whether a soluble factor mediated IFN-γR down-regulation, BMMs were infected at a low multiplicity (MOI = 5) with a wt Lm strain expressing enhanced GFP. Both infected (GFP^hi) and uninfected (GFP^lo) BMM in these cultures down-regulated IFN-γR1 expression (Fig. 3 B). In contrast, BMM infected with ∆Hly Lm that expressed enhanced GFP failed to down-regulate IFN-γR. This provided a mechanistic basis for the reduction in responsiveness of wt Lm–infected BMM to IFN-γ.

**IFN-γR is selectively down-regulated on antigen-presenting cell populations**

When C57BL/6 mice were infected i.v. with a sublethal dose of wt Lm (10,000 cfu), both splenic myeloid (CD11b+) and B lymphocyte (B220+CD19+) populations showed significant reductions in IFN-γR1 staining from 24 to at least 48 hpi (Fig. 3 A). IFN-γR1 staining remained low on CD11c+ gated DCs for at least 79 hpi (Fig. 3 A and see Fig. 5 A). Cell surface IFN-γR1 staining was also slightly, but not significantly, reduced on NK1.1+CD3+ NK cells (P > 0.05). However, no reduction was seen in IFN-γR1 staining on gated CD3+ T cells. These results indicated that down-regulation of IFN-γR1 selectively occurs on APC populations during the early stages of systemic infection with virulent *L. monocytogenes*. Furthermore, the results showed that IFN-γR1 was down-regulated on nearly all APCs in *L. monocytogenes*–infected mice (Fig. 3 A), despite the fact that only a fraction of APCs are infected with live bacteria at the infection dose used (10^4). We thus hypothesized that a soluble factor released from *L. monocytogenes*–infected cells was responsible for IFN-γR1 down-regulation.

A soluble factor released from infected cells mediates IFN-γ down-regulation and suppressed responses to IFN-γ

As a first step to directly evaluate whether a soluble factor mediated IFN-γR down-regulation, BMMs were infected at a low multiplicity (MOI = 5) with a wt Lm strain expressing enhanced GFP. Both infected (GFP^hi) and uninfected (GFP^lo) BMM in these cultures down-regulated IFN-γR1 expression (Fig. 3 B). In contrast, BMM infected with ∆Hly Lm that expressed enhanced GFP failed to down-regulate IFN-γR.
IFN-αβ is responsible for IFNGR down-modulation

We asked whether other inflammatory stimuli might also induce macrophages to secrete factors that down-regulate the IFNGR. C57BL/6 and MyD88−/− BMMs were thus treated with TLR agonists or infected with wt Lm as a control. Similar IFNGR1 down-regulation was seen in both B6 and B6.MyD88−/− BMMs that were infected with wt Lm, indicating that MyD88-dependent TLR signaling was dispensable for induction of the soluble IFNGR down-regulating factor by live cytosolic L. monocytogenes (Fig. 4 A). Nonetheless, treatments with specific TLR agonists (including non-methylated CpG oligodeoxynucleotides [ODNs], poly I:C, and, to a lesser extent, LPS) did induce significant IFNGR1 down-regulation (Fig. 4 A). In some cases, these treatments required MyD88 expression by the BMM. Scrambled control ODNs and the triacyl-lipopeptide Pam3Cys failed to elicit down-regulation of IFNGR1.

Type I IFNs are produced by macrophages in response to cytosolic (but not ΔHly) L. monocytogenes infection, as well as by stimulation with CpG ODN, LPS, and pIC. To determine whether IFN-αβ might be the host factor responsible for IFNGR down-regulation, we evaluated IFNGR1 surface expression on macrophages from IFNAR1−/− mice after wt Lm infection. Strikingly, the infected IFNAR−/− macrophages failed to significantly down-regulate IFNGR1 or IFNGR2 (Fig. 4 B). We also used reciprocal transfers of sterile filtered supernatants from infected C57BL/6 or IFNAR1−/− donor

![Image of Figure 4](link)
BMMs to induce IFNGR down-regulation on uninfected recipient C57BL/6 or IFNAR1−/− BMMs. Staining for cell surface IFNGR1 on recipient BMM revealed that only those macrophages expressing the IFNAR were capable of significantly down-regulating IFNGR1 (Fig. 4 C). Thus, IFNAR signaling was necessary for the response to, but not the induction of, the factors that down-regulate the IFNGR.

To determine whether type I IFN was sufficient to mediate IFNGR down-regulation, we treated C57BL/6 BMM with a panel of recombinant commercial mouse cytokines. Down-regulation of IFNGR1 was not seen in macrophages treated with IL-6 or IL-10 (Fig. 4 D), two cytokines which are known to suppress IFN-γ signaling (Nagabhushanam et al., 2003; Dikopoulos et al., 2005; Carrero et al., 2006; Murray, 2007). In addition, IFNGR down-regulation was not seen in cells treated with recombinant IL-28/IFN-λ, a cytokine which shares signaling components with IL-10 and IFN-αβ (Donnelly et al., 2004). However, recombinant IFN-β induced a similar degree of IFNGR1 down-regulation as seen during wt Lm infection (Fig. 4 D). As expected, IFNGR1 down-regulation was not induced by IFN-β treatment of IFNAR1−/− BMM (unpublished data). These data indicate that IFNAR signaling is necessary and sufficient for down-regulation of IFNGR1.

Increased resistance of IFNAR1−/− mice to L. monocytogenes infection correlates with increased macrophage activation and requires IFN-γ

The results in the previous sections suggested that APC populations from IFNAR1−/− mice might respond better to IFN-γ and, thus, more efficiently clear in vivo bacterial infections. Indeed, IFNGR1 and MHCI cell surface staining were dramatically reduced on CD11c+CD3− DCs from wt Lm–infected B6 mice when compared with the same population from infected IFNAR1−/− or uninfected C57BL/6 mice (Fig. 5 A). Similar results were seen on gated Ly6G−CD11b+ inflammatory monocytes (unpublished data). It was previously reported that infection with wt Lm elicits similar serum concentrations of IFN-γ in IFNAR−/− and IFNAR+/+ mice (Auerbuch et al., 2004). Thus, the respective increases in MHCI expression seen in infected B6 and B6.IFNAR1−/− mice are not explained by differences in the amounts of IFN-γ produced in each mouse strain.

We further demonstrated that the differences in MHCI expression were the result of IFN-γ, rather than other factors, by evaluating staining on cells from B6 and B6.IFNAR1−/− mice given a neutralizing antibody to IFN-γ (XMG1.2) before wt Lm infection. The XMG1.2 treatment reduced MHCI expression on gated APCs to a similar basal level in both mouse strains (Fig. 5 A). Thus, although MHCI expression was increased by the infection in APCs from both IFNAR–expressing and IFNAR1–deficient mice, the response was more pronounced in the IFNAR1−/− animals.

Bacterial burdens present in the livers of infected B6, B6.IFNAR1−/−, and IFN-γ–depleted B6.IFNAR1−/− mice were also determined at 79 hpi with wt Lm. Organs from the control B6.IFNAR1−/− mice harbored ~3–4 logs fewer bacteria when compared with C57BL/6 mice (Fig. 5 B), confirming the heightened resistance of IFNAR1−/− mice to wt Lm infection. However, this heightened resistance was completely abrogated by antibody-mediated depletion of IFN-γ in the B6.IFNAR1−/− mice pretreated with 500 µg

Figure 5. The resistance of IFNAR−/− APCs to IFNGR down-regulation correlates with their increased activation by IFN-γ and increased IFN-γ-dependent resistance of IFNAR−/− mice to systemic L. monocytogenes infection. (A) B6.IFNAR1−/− and congenic C57BL/6 mice were treated with PBS or 500 µg of anti–IFN-γ (XMG1.2) diluted in PBS 17 h before infection with a sublethal dose of wt Lm (9,000 cfu). Splenic and livers were harvested 72 h later. Gated monocytes and DCs were analyzed for cell surface MHCI expression. The MFI for each histogram is indicated in parentheses. Data are representative of results from three to four mice per group. (B) Livers from the infected mice were homogenized and dilution plated to determine bacterial burdens. Each point indicates an individual mouse. Bars indicate the mean values. The asterisk indicates a p-value of <0.05. Experiments were repeated twice.
neutralizing anti–IFN-γ antibody (XMG1.2). Indeed, the bacterial burdens in the IFN-γ–depleted IFNAR1−/− mice were not significantly different from those seen in control or IFN-γ–depleted C57BL/6 mice. Thus, the heightened responsiveness of IFNAR1−/− mice to IFN-γ accounts for their increased resistance to L. monocytogenes infection.

Concluding remarks

Our studies reveal that production of IFN-αβ early after L. monocytogenes infection down-regulates ifngr1 transcription and, hence, reduces surface expression of the IFNGR by ~50–60%. Despite the partial nature of this reduction in IFNGR expression, the induction of IFN-γ–dependent gene expression by APCs is clearly affected both in vitro and in vivo. As shown in this paper, cells infected with L. monocytogenes respond poorly to IFN-γ, and supernatant from these cells impairs transcriptional and translational up-regulation of IFN-γ–inducible genes. To our knowledge, the ability of IFN-αβ to down-regulate IFNGR expression by APCs has not been previously reported. However, our findings do provide an explanation for the previously described ability of IFN-αβ to interfere with binding of IFN-γ to macrophages and B cells (Thompson et al., 1993; Yoshida et al., 1988). Our findings are also consistent with several older studies that showed that IFN-αβ treatment antagonizes the response of mouse and mature human macrophages to treatment with IFN-γ (Zhang et al., 1985; Inaba et al., 1986; Yoshida et al., 1988).

We speculate that the ability of IFN-αβ to suppress IFNGR expression has evolved to permit the integration of coincident signals that occur during infection with agents that induce concurrent expression of both IFN-αβ and IFN-γ. By suppressing responsiveness of APCs to IFN-γ, IFN-αβ may prioritize the development of an antiviral IFN-αβ–type response to more effectively limit viral infections. The ability of IFN-αβ to suppress IFN-γ–type responses may also benefit the host by limiting collateral damage that might otherwise result from the rapid activation of macrophages and other APCs by IFN-γ. Indeed, IFN-β is commonly used to treat relapsing-remitting multiple sclerosis, an inflammatory autoimmune disease of the central nervous system (Hummer et al., 2006; Borden et al., 2007). Likewise, IFN-αβ reduces disease severity in the murine multiple sclerosis model of experimental autoimmune encephalitis. Recent work shows the protective effect of IFN-αβ in experimental autoimmune encephalitis requires IFNAR1 expression on mouse myeloid cells (Prinz et al., 2008). In light of our findings, one may speculate that a key effect of IFN-αβ is to down-regulate IFNGR expression on myeloid cells, thereby reducing stimulation of autoimmune T cells and the consequences of IFN-γ produced by such T cells. Given that IFN-αβ does not reduce IFNGR expression in T cells, the integration of IFN-αβ and IFN-γ signals in T cells must entail distinct mechanisms.

IFNAR1−/− mice have been shown to have heightened resistance to systemic L. monocytogenes infection, as judged by reduced bacterial burdens beginning within 3 or 4 d of systemic infection (Auerbuch et al., 2004; Carrero et al., 2004; O’Connell et al., 2004). L. monocytogenes–infected IFNAR−/− mice also produce lower amounts of IL-10 (perhaps because of increased splenocyte apoptosis) and increased production of IL-12 and TNF when compared with control animals (Auerbuch et al., 2004; Carrero et al., 2006). We propose that there may be a common mechanistic basis for such increased resistance. Given our data and previous results that IFN-γ enhances TNF production and suppresses IL-10 production by macrophages (Chomarat et al., 1993; Bundschuh et al., 1997; Déry and Bissonnette, 1999), we propose that the increased resistance of IFNAR−/− to L. monocytogenes is a result of their failure to down-regulate the IFNGR. Consistent with this model, we show that APCs are more highly activated after infection of IFNAR−/− mice and that these mice more efficiently limit bacterial replication at early times after infection. Indeed, both this increased APC activation and increased resistance to infection are completely abrogated by depletion of IFN-γ. A potential alternative explanation of our findings is that the increased IL-10 in the WT, but not IFNAR1−/−, mice suppresses the production of IFN-γ. Indeed, IL-10 suppresses IFN-γ production induced by treatment of cultured splenocytes from SCID mice with killed L. monocytogenes (Tripp et al., 1993). However, it was previously shown, and our findings confirm, that sera of both control and IFNAR−/− mice infected with live L. monocytogenes contain similar amounts of IFN-γ (Auerbuch et al., 2004). Thus, we favor the interpretation that IFN-αβ production in WT mice impairs responsiveness of APCs to IFN-γ and, thus, the host’s ability to limit bacterial replication and dissemination.

Recently, IFNAR−/− mice have also been shown to resist infection with several additional pathogenic bacteria (Stanley et al., 2007; Qu et al., 2008; Martin et al., 2009; Shahangian et al., 2009). Some of these bacteria, such as M. tuberculosis and Chlamydia trachomatis, are known to suppress cellular responses to IFN-γ (Belland et al., 2003; Kincaid and Ernst, 2003; Pai et al., 2003). It thus appears likely that the mechanism for antagonistic cross talk between IFN-αβ and IFN-γ that we describe in this paper also impacts susceptibility to these other pathogenic bacteria. Additional understanding of the mechanisms regulating IFNGR down-regulation by IFN-αβ may lead to improved treatments for a variety of infectious and inflammatory diseases.

MATERIALS AND METHODS

Mice. IFNAR−/−, IL-6−/−, IFNGR−/−, and IFN-γ−/− mice were crossed to C57BL/6J (The Jackson Laboratory) for >10 generations. B6.IFNAR1−/− mice were originally obtained from DA. Portnoy (University of California, Berkeley, Berkeley, CA). STAT1−/− and isogenic 129/Sv mice were obtained from Taconic. Mice were housed in the National Jewish Health Biological Resource Center. All studies were approved by the National Jewish Health Institutional Animal Care and Use Committee.

Mouse infections. Female mice between 8 and 10 wk of age were used for all in vivo experiments. Mice were infected (tail vein) with 0.5–2 × 104 cfu of log-phase mouse passaged L. monocytogenes strain 10403S. 24–96 h later, spleens and livers were harvested for analysis. Spleens were treated with 0.3% collagenase type IV (Worthington Biochemical Corporation) to release phagocytic...
and adherent cell populations then processed into single cell suspensions for staining and flow cytometry. Bacterial CFUs in infected tissues were determined by dilution plating as previously described (Humann et al., 2007).

**Macrophage cultures and cell lines.** To culture BMMs, cells were flushed from both femurs of mice and cultured for 6 days in BM macrophage media (DMEM supplemented with 10% FBS, 1% sodium pyruvate, 1% L-glutamine, 1% penicillin/streptomycin, 2-mercaptoethanol, and 10% L-cell conditioned media). Fresh media was added at day 3 and BMMs were used for experiments on day 7. RAW264.7 macrophage cells stably transfected with a CIITApIV-luciferase construct (RAW-CIITApIV reporter cells) were provided by J. Ernst (New York University, New York, NY; Fortune et al., 2004). RAW.GAS6 reporter macrophages were generated in our laboratory by stable transfection with linearized pHTS-GAS (Biomyx Technology). RAW.GAS6 reporter macrophages were generated in our laboratory by stable transfection with linearized pHTS-GAS (Biomyx Technology). RAW-CIITApIV and RAW-GAS6 reporter cells were cultured with selection in 400 μg/ml neomycin or 100 μg/ml hygromycin, respectively.

**Infection of cultured macrophages and immunoblotting.** BMM or RAW reporter cell lines were cultured overnight in antibiotic-free media and then infected with log-phase *L. monocytogenes* 1043S (wt Lm) or the isogenic ΔHly strain provided by D.A. Portnoy. Macrophages were infected at MOI = 1–5 for 30 min, washed three times in PBS, and grown fresh media. At 1 h after infection, gentamicin was added to a concentration of 50 μg/ml to kill extracellular bacteria. For immunoblotting studies, control or infected macrophages were treated with 100 U/ml IFN-γ for 2 or 6 h. Cells were rinsed in PBS and lysed in SDS-PAGE buffer (62.5 mM Tris-HCl, pH 6.8, 2% SDS, 10% glycerol, 50 mM DTT, and 0.01% bromophenol blue) supplemented with HALT phosphatase and protease inhibitors (Thermo Fisher Scientific). Lysates were separated by SDS-PAGE and immunoblotted with rabbit anti-pY701 STAT1, total STAT1, or mouse anti-actin using commercial antibodies (Cell Signaling Technology and Millipore) followed by secondary HRP-labeled anti-rabbit and anti-mouse (Thermo Fisher Scientific).

**Luciferase assay.** Reporter cells were plated at 2 × 10⁴ per well in 2-well plates and mock-infected or infected with WT or ΔHly *L. monocytogenes*. At 2 hpi, the culture media was replaced with fresh media containing 50 μg/ml gentamicin plus 0 or 100 U/ml of recombinant mouse IFN-γ (Invitrogen). Lysates were harvested at 10 hpi using lysis buffer from the Enhanced Luciferase Assay kit (BD) and frozen at −20°C. Luminescence was measured using injectors and kit reagents on a Synergy 2 reader with injector (BioTek).

**Flow cytometry.** Colloquenase-treated splenocytes were incubated 1 min in ACK lysis buffer to lyse red blood cells then pelleted (Humann et al., 2007). BMMs were lifted from culture dishes with Trypsin (Speciality Media) and pelleted. Fc receptors were blocked before staining using supernatant from ACK lysis buffer to lyse red blood cells then pelleted (Humann et al., 2007). Flow cytometry used Cytofix/Cytoperm solutions (BD) or DakoCytomation CyAn (Dako) machines and analyzed using FlowJo software (Tree Star, Inc.).

**TLR and cytokine stimulations.** Uninfected BMMs were treated with the indicated TLR agonists and cytokines for 8 h before analysis. CpG, scrambled CpG, and ultrapure LPS (InvivoGen) were used at 1 μg/ml (CpG) and 10 mg/ml (LPS). Poly I:C (GE Healthcare) was used at 10 µg/ml. Pam3Cys was a gift from R. Kedl (Colorado University, Denver, CO) and used at 1 µg/ml. Recombinant mouse IL-6, IL-10, and IL-28 (eBioscience) were used at respective final concentrations of 0.01, 0.3, and 0.2 ng/ml. Recombinant mouse IFN-β (R&D Systems) was used at 100 U/ml.
