WASp-deficient B cells play a critical, cell-intrinsic role in triggering autoimmunity

Shirly Becker-Herman,1,7 Almut Meyer-Bahlburg,1,7 Marc A. Schwartz,2 Shaun W. Jackson,1,7 Kelly L. Hudkins,3 Chaohong Liu,5 Blythe D. Sather,1,7 Socheath Khim,1,7 Denny Liggitt,4 Wenxia Song,5 Gregg J. Silverman,6 Charles E. Alpers,3 and David J. Rawlings1,2,7

Patients with the immunodeficiency Wiskott-Aldrich syndrome (WAS) frequently develop systemic autoimmunity. Here, we demonstrate that mutation of the WAS gene results in B cells that are hyperresponsive to B cell receptor and Toll-like receptor (TLR) signals in vitro, thereby promoting a B cell–intrinsic break in tolerance. Whereas this defect leads to autoantibody production in WAS protein–deficient (WASp−/−) mice without overt disease, chimeric mice in which only the B cell lineage lacks WASp exhibit severe autoimmunity characterized by spontaneous germinal center formation, class-switched autoantibodies, renal histopathology, and early mortality. Both T cell help and B cell–intrinsic TLR engagement play important roles in promoting disease in this model, as depletion with anti-CD4 antibodies or generation of chimeric mice with B cells deficient in both WASp and MyD88 prevented development of autoimmune disease. These data highlight the potentially harmful role for cell-intrinsic loss of B cell tolerance in the setting of normal T cell function, and may explain why WAS patients with mixed chimerism after stem cell transplantation often develop severe humoral autoimmunity.

Wiskott-Aldrich syndrome (WAS) is an X-linked immunodeficiency characterized by recurrent infections, abnormal lymphocyte function, thrombocytopenia, and eczema, as well as a significantly increased risk for systemic autoimmunity (Sullivan et al., 1994). The affected gene, WAS protein (WASp), encodes a multidomain protein, WASp, which is exclusively expressed in hematopoietic cells, where it is involved in signal transduction to the actin cytoskeleton (Thrasher 2002). Signaling defects resulting from WASp deficiency have been analyzed most extensively in T lymphocytes. After TCR ligation, WASp−/− T cells show decreased Ca2+ flux, reduced actin polymerization, diminished antigen receptor (AR) endocytosis, and abnormal proliferation caused by deficient IL-2 secretion (Bouma et al., 2009). WASp deficiency impacts additional lineages, including B cells, NKT cells, neutrophils, DCs, monocytes, and platelets. These defects may contribute independently or in combination to mediate the complex clinical features of WAS.

The functional defect that promotes autoimmunity in WAS is of great interest. Prevalence of autoimmune symptoms in WAS is high; in one study >70% of patients had at least one autoimmune episode, including autoimmune cytopenias, arthritis, vasculitis, or renal disease, and many of these patients suffered from recurrent or multiple autoimmune features (Sullivan et al., 1994; Dupuis-Girod et al., 2003). Autoimmunity typically presents early in life, is often refractory to therapy, and is associated with a worse clinical prognosis (Imai et al., 2004).
Consistent with these observations in patients, \textit{WASp}^-/- mice develop high-titer, anti–double-stranded (ds) DNA antibodies early in life (Humblet-Baron et al., 2007). However, only minimal autoantibody-mediated disease features have been reported in this strain (Humblet-Baron et al., 2007; Nikolov et al., 2010), suggesting such antibodies are relatively nonpathogenic.

Interestingly, a significant proportion of WAS patients treated using stem cell transplantation develop systemic autoimmunity that is not predicted by pretransplant disease features (Ozshahin et al., 2008). This complication is strongly associated with mixed/split chimerism, indicating that residual WAS mutant lymphocytes can mediate autoimmune disease despite the coexistence of normal donor cells. These data imply that, in a chimeric setting, dysregulated function within a candidate lymphoid population is unmasked by restoration of functional activity within other hematopoietic lineages.

Notably, several recent studies including work from our laboratory demonstrated defects in both homeostasis and function of \textit{WASp}^-/- regulatory T cells (T reg cells). These observations suggested that altered T reg cell activity might predispose to autoantibody production in \textit{WASp}^-/- mice (Humblet-Baron et al., 2007; Maillard et al., 2007; Marangoni et al., 2007). In the current study, we make the surprising observation that female \textit{WASp}^-/- mice generate anti–nuclear antibodies at rates and titers equivalent to \textit{WASp}^-/- mice, even though carrier animals have an essentially normal T reg cell compartment because of a strong selective advantage for \textit{WASp}^+ T reg cells. Based on this observation, we tested the alternative hypothesis that autoantibody production in \textit{WASp}^-/- mice results from a B cell–intrinsic defect. Consistent with this idea, we show that in the setting of WT T cells, DCs, and other hematopoietic lineages, \textit{WASp}^-/- B cells are necessary and sufficient for development of autoauto题ations. Collectively, our results suggest that B cell receptor (BCR)/Toll-like receptor (TLR) co-engagement on \textit{WASp}^+/- B cells mediates loss of tolerance, which, in the presence of WT T cells, drives development of severe autoimmune disease.

RESULTS

\textit{WASp}^+/- carrier females develop high–titer anti–dsDNA antibodies

We previously reported that WASp is essential for normal T reg cell homeostasis (Humblet-Baron et al., 2007), leading to the hypothesis that autoantibody production in \textit{WASp}^-/- mice results from a lack of T reg cell–mediated immunosuppression. To address this idea, we analyzed \textit{WASp}^+/- female mice in which >90% of peripheral T reg cells are \textit{WASp}^+ because of a selective advantage over T reg cells expressing the mutated X-linked WASp allele (Humblet-Baron et al., 2007). Surprisingly, we found no difference in the amount of anti–dsDNA autoanti-bodies between \textit{WASp}^-/- and \textit{WASp}^+/- mice (Fig. 1 A). T reg cells isolated from \textit{WASp}^+/- mice were functionally indistinguishable from WT T reg cells in suppressing T cell proliferation (Fig. S1 A). Collectively, these data imply that impaired T reg cell function is unlikely to explain the development of autoantibodies in \textit{WASp}^-/- mice.

\textit{WASp}^-/- B cells are sufficient for high–affinity, class–switched autoantibody production

We next sought to determine if autoantibody production in \textit{WASp}^-/- mice is a B cell–intrinsic phenomenon using a mixed BM chimera model. Of the multiple strategies we tested, optimal B cell reconstitution with minimal mixed chimerism in other hematopoietic lineages was achieved by transplanting a mix of 20% \textit{WASp}^-/- or WT BM with 80% μMT BM into lethally (1050 cGy) irradiated μMT recipients. To eliminate transfer of previously activated B cell populations, we used BM from very young donors (4–5 wk) depleted of plasma B cells. Donor sera were also prescreened to verify absence of dsDNA antibodies. After reconstitution, B cells were entirely donor derived (\textit{WASp}^-/- or WT), >95% of CD3^+ T cells and CD4^+ Foxp3^+ T reg cells were \textit{WASp}^+, and >85% of both NK and myeloid cells were \textit{WASp}^+ (Fig. S1 B). Consistent with a B cell–intrinsic role for WASp, recipients of \textit{WASp}^-/- BM cells (hereafter referred to as \textit{WASp}^-/- chimeras) developed high titers of anti–dsDNA autoantibodies, whereas WT recipients did not (Fig. 1 B). A proportion of \textit{WASp}^-/- chimeras did not have high anti–dsDNA antibody titers at 16 wk after transplant, but this proportion decreased when mice were analyzed at later time points (unpublished data), suggesting that \textit{WASp}^-/- chimeras experience a progressive loss in B cell tolerance as they age. Because \textit{WASp}^-/- T cells are functionally abnormal, we predicted that the presence of WT T cells in \textit{WASp}^-/- chimeras may drive more efficient germinal center (GC) responses, resulting in class switch recombination (CSR) and affinity maturation. To test this idea, we evaluated anti–dsDNA autoantibody affinity using high and low stringency ELISA washing conditions. Anti–dsDNA autoantibodies were detected after high-stringency washing in \textit{WASp}^-/- chimeras as early as 12 wk after transplant, compared with a lack of consistent high–titer anti–dsDNA autoantibody production in 12 wk old \textit{WASp}^-/- mice (Fig. 1 C). Next, we analyzed the subclass of anti–dsDNA autoantibodies. Strikingly, \textit{WASp}^-/- mice generated primarily IgG3 autoantibodies, whereas \textit{WASp}^-/- chimeras generated IgG2b and IgG2c, but little or no IgG3, anti–dsDNA autoantibodies (Fig. 1, D–F). Consistent with our hypothesis that WT T cells drive GC formation in \textit{WASp}^-/- chimeras, we found greater numbers of B220^+PNA^+ splenocytes in \textit{WASp}^-/- compared with WT chimeras (Fig. 1 G). Additionally, histological analysis of splenic sections revealed consistently larger and more frequent PNA^+ GCs in \textit{WASp}^-/- versus WT chimeras (Fig. 1 H). Widespread spontaneous GC formation, as detected in \textit{WASp}^-/- chimeras, is a characteristic feature of several previously described autoimmune–susceptible mouse strains (Luzina et al., 2001).

To determine whether other autoantibody specificities produced by \textit{WASp}^-/- mice are recapitulated in \textit{WASp}^-/- chimeras, custom microarray slides were prepared with various DNA–associated antigens and apoptotic cell epitopes and screened using sera from WT, \textit{WASp}^-/-, WT chimera, and \textit{WASp}^-/- chimera mice. IgG antibody reactivity to chromatin, dsDNA, ssDNA, and the apoptosis associated neo–determinant
malondialdehyde (MDA) as a conjugate with low-density lipoprotein (MDA-LDL), was detected in both WASp−/− and WASp+/− chimera sera, but not in WT mice or WT chimeras (Fig. 1 I). ELISAs confirmed the presence of anti–MDA-LDL antibodies in WASp−/− mice and chimeras, and further subclass analysis revealed that, in a similar pattern to anti-dsDNA antibodies, WASp−/− mice produced primarily IgG3 antibodies, whereas WASp+/− chimeras produced IgG2b and IgG2c anti–MDA-LDL antibodies (Fig. S2).

These combined experiments support the conclusion that WASp deficiency in B cells is sufficient for development of high-affinity, class-switched DNA and apoptotic antigen–specific autoantibodies in the presence of WT-derived hematopoietic cells.

**WASp−/− chimeras develop systemic autoimmunity and exhibit early mortality**

Despite the presence of high-titer anti-dsDNA autoantibodies, WASp−/− mice on a C57BL/6 background do not develop systemic autoimmune features or increased mortality (unpublished data). To assess the longer-term consequences of B cell-specific WASp-deficiency, cohorts of WASp−/− versus WT chimeras were followed for >1 yr. Strikingly, WASp−/− chimeras exhibited increased mortality beginning

**Figure 1.** WASp−/− B cells are sufficient for high-affinity, class-switched autoantibody production and spontaneous GC formation. IgG anti-dsDNA autoantibody ELISAs in 6.5–12-mo-old female WASp+/−, WASp−/−, and WT mice (A) and WT and WASp−/− chimeras at 16 wk after transplant (B). BWF1: lupus-prone positive control, NZB/NZW-F1, 8 mo old. Sera diluted 1:200; each dot represents an individual animal. (C) ELISAs with low versus high stringency washing conditions used to detect high-affinity IgG anti-dsDNA antibodies in WASp−/− and WASp+/− chimeric mice (12 wk old or 12 wk after transplant). Each pair of bars represents an individual animal. (D–F) ELISAs to detect IgG subclass-specific anti-dsDNA antibodies. (WASp−/− chimeras, n = 29; WASp−/− mice, n = 10; 4 mo after transplant or 4 mo old, respectively). (G) Percentage of splenic B cells staining positive for PNA by flow cytometry in 6–8-mo-old WT (n = 7) and WASp−/− (n = 7) mice, as well as WT (n = 5) and WASp−/− (n = 4) BM chimeras 6–8 mo after transplant. (H) Immunofluorescent staining of splenic sections from BM chimeras showing representative follicles using B220 (red) CD3 (blue) and PNA (green); 10× objective was used for image capture; bars, 100 µm. (I) Antigen microarray showing IgG reactivity of WT, WASp−/−, WT chimera, and WASp−/− chimera sera with ssDNA, dsDNA, MDA–LDL, and chromatin. Sera from WT and WASp−/− mice (1 yr) and chimeric mice (6 mo after transplant). Scale shows digital fluorescence intensity units; 600 represents threshold for reactivity as described in Materials and methods. These data are representative of 4 independent experiments with 20–30 mice per experiment. *, P < 0.05; **, P < 0.005; ***, P < 0.0005.
WASp-deficient B cells trigger autoimmunity

WASp-deficient B cells trigger autoimmunity | Becker-Herman et al.

at ∼7 mo after transplant, with only 50% survival at 12 mo compared with 97% in WT recipients (Fig. 2 A).

To better characterize disease features, we monitored renal function and performed extensive histopathological analyses in several cohorts. To screen for renal disease, we measured urine protein/creatinine ratio. WASp−/− chimeras developed progressive proteinuria beginning 5–6 mo after transplant (Fig. 2 B). Next, we analyzed the kidneys of WASp−/− chimeras for histological abnormalities and identified widespread glomerular lesions exhibiting prominent accumulations of eosinophilic thrombuslike material within glomerular capillaries, as well as increases in mesangial matrix accumulation, focal mesangiolysis, and glomerular basement membrane splitting (Fig. 2 C, II). In contrast, WT chimeras were normal in appearance (Fig. 2 C, I). MAC-2 staining of kidney sections revealed macrophage infiltration of glomeruli from WASp−/−, but not WT, chimeras (Fig. 2 C, III and IV). Notably, oil red O staining of frozen sections identified the presence of neutral lipids within glomeruli of WASp−/− chimeras, but not in WT chimeras (Fig. 2 C, V and VI), which appeared to correlate with the intracapillary accumulations of eosinophilic material. Immunofluorescent staining demonstrated deposition of IgG2b, IgG2c, and complement C3 in WASp−/− chimera glomeruli (Fig. 2 D, II, IV, and VI), whereas less C3 deposition and little to no IgG2b and IgG2c deposition was detected in WT chimeras (Fig. 2 D, I, III, and V). However, there were no differences in deposition of IgG, IgA, and IgM. Glomerular thrombi appeared moderately electron dense by electron microscopy (Fig. 2 E, left), and higher magnification analysis revealed focal regions of fibrillar organization, consistent with co-deposited immune complexes (Fig. 2 E, right, arrows). Many of the thrombi had vacuoles of differing sizes that appeared to be lipid or lipoprotein accumulations (Fig. 2 E, arrowheads). In contrast, liver, lungs, joints, and gastrointestinal tract appeared unaffected in WASp−/− chimeras (unpublished data). These results demonstrate that WASp−/− chimeras develop systemic autoimmune disease characterized by generation of autoantibodies, severe renal histopathology, and early mortality.

WASp−/− B cells are hyperresponsive to key activation signals in vitro and in vivo

We next sought to determine whether WASp−/− B cells exhibit an altered response to BCR engagement. WASp−/−
spleenic follicular mature (FM) B cells consistently exhibited a higher peak Ca\(^{2+}\) flux in comparison with WT FM B cells after BCR stimulation, a difference that was most pronounced when using lower dose anti-IgM (Fig. 3 A). IgM surface expression was equivalent or slightly lower in WASp\(^{-/-}\) B cells, indicating that altered BCR density could not account for our findings (Fig. 3 A). Experiments using Ca\(^{2+}\)-free media and/or the Ca\(^{2+}\) ATPase-inhibitor thapsigargin indicated that WASp\(^{-/-}\) FM B cells exhibit enhanced extracellular Ca\(^{2+}\) influx after BCR engagement (Fig. 3 D and Fig. S3 A).

Next, we evaluated proliferation downstream of BCR engagement by measuring CFSE dilution. We observed increased proliferation in WASp\(^{-/-}\) FM B cells as compared with WT controls in response to anti-IgM stimulation (Fig. 3 B). Intriguingly, both LPS and CpG stimulation also lead to increased cell cycling (Fig. 3 B), indicating that hyperresponsiveness was not limited to BCR engagement. WASp\(^{-/-}\) B cells also displayed slightly increased CD25 and reduced CD62L expression compared with WT B cells, which is consistent with a more activated state after stimulation (Fig. S3 B). To exclude the possibility that these observations were caused by altered lymphoid environments, we generated BM chimeras consisting of 50% Ly5.1+ WT and 50% Ly5.2+ WASp\(^{-/-}\) B cells. Ca\(^{2+}\) flux and proliferation experiments using cells isolated from transplanted mice led to findings that mirrored the aforementioned results (Fig. 3, D and E).

WASp plays an important role in cytoskeletal rearrangement, leading us to hypothesize that a defect in BCR internalization might explain the observed increase in AR responsiveness. Although down-regulation in BCR surface expression was detected in WASp\(^{-/-}\) B cells after BCR stimulation, this decrease was much less pronounced over the first 10 min compared with WT cells (Fig. 3 C). Together, these data indicate that WASp\(^{-/-}\) B cells are hyper-responsive to BCR stimulation, possibly because of decreased receptor internalization.

### CD4 T cell depletion reduces autoantibody production and prevents disease in WASp\(^{-/-}\) chimeras

We hypothesized that the presence of WT T cells was critical for the formation of GCs and IgG2b subclass CSR, and for development of systemic autoimmune disease in WASp\(^{-/-}\) chimeras. To test this hypothesis, we treated a new cohort of WT and WASp\(^{-/-}\) chimeras weekly with monoclonal CD4-depleting antibody (Fig. S4). Although WASp\(^{-/-}\) chimeras depleted of CD4 T cells still produced IgG anti-dsDNA antibodies, albeit at lower levels than in untreated WASp\(^{-/-}\) chimeras, CD4 depletion completely prevented IgG2c anti-dsDNA production (Fig. 4 A). In contrast, IgG3 autoantibodies were not eliminated by CD4 depletion (Fig. 4 A). In addition, although lower in titer than untreated WASp\(^{-/-}\) chimeras, IgG2b autoantibodies were significantly higher in CD4-depleted WASp\(^{-/-}\) chimeras than in WT chimeras (Fig. 4 A). As expected, WASp\(^{-/-}\) chimeras depleted of CD4 T cells did not exhibit an increase in GC phenotype (B220+ PNA+FAS+) splenocytes (Fig. 4 B) and lacked spontaneous GC formation in splenic sections (Fig. 4 C). Finally, CD4 depletion prevented the glomerular pathology and IgG2b/c and C3 deposition that were observed in untreated or isotype antibody-treated WASp\(^{-/-}\) chimeras (Fig. 4 D). These data support our hypothesis that WT T cells in WASp\(^{-/-}\) chimeras drive CSR and affinity maturation of autoreactive WASp\(^{-/-}\) B cells, leading to production of pathological autoantibodies and systemic autoimmune disease.

### B cell MyD88 signaling is required for autoimmunity in WASp\(^{-/-}\) BM chimeras

Because we observed enhanced proliferation of WASp\(^{-/-}\) B cells in response to in vitro TLR engagement, we asked whether B cell–intrinsic TLR signaling is required for autoantibody production in WASp\(^{-/-}\) BM chimeras. WASp\(^{-/-}\) MyD88\(^{-/-}\) double-deficient mice were generated and used as donors to generate cohorts of BM chimeras in which all B cells lacked both WASp and MyD88, whereas all other hematopoietic lineages were WT-derived. WASp\(^{-/-}\) MyD88\(^{-/-}\) chimeras did not produce IgG (or IgG subclass) anti-dsDNA antibodies (Fig. 4 A), demonstrated no increase in PNA+FAS+B cells (Fig. 4 B), and did not develop spontaneous GC formation on splenic sections (Fig. 4 C). In addition, WASp\(^{-/-}\) MyD88\(^{-/-}\) chimeras were completely protected from developing renal pathology and glomerular IgG2b/c and C3 deposition (Fig. 4 D). These results indicate that B cell–intrinsic MyD88 signaling is essential for production of anti-dsDNA antibodies, GC formation, and development of systemic autoimmune disease in WASp\(^{-/-}\) chimeras.

### DISCUSSION

Autoimmunity is a hallmark of WAS, typically manifesting as humoral autoimmunity in up to 70% of WAS patients (Sullivan et al., 1994; Dupuis-Girod et al., 2003). Additionally, a large number of patients develop systemic autoimmunity after stem cell transplantation, and this complication strongly correlates with mixed chimerism (Ozsahin et al., 2008). Here, we demonstrate that autoantibody production in WASp\(^{-/-}\) mice does not result from a T cell-mediated immunosuppression. We next addressed whether WASp\(^{-/-}\) B cells might trigger autoimmunity using mixed BM chimeras where only B cells lacked expression of WASp. Our data indicate that WASp\(^{-/-}\) B cells play a primary role in driving autoimmunity; indicating that a single gene defect in B cells, yielding a modest hyperresponsiveness to BCR engagement by measuring CFSE dilution. We observed increased proliferation in WASp\(^{-/-}\) FM B cells as compared with WT controls in response to anti-IgM stimulation (Fig. 3 B). Intriguingly, both LPS and CpG stimulation also lead to increased cell cycling (Fig. 3 B), indicating that hyperresponsiveness was not limited to BCR engagement. WASp\(^{-/-}\) B cells also displayed slightly increased CD25 and reduced CD62L expression compared with WT B cells, which is consistent with a more activated state after stimulation (Fig. S3 B). To exclude the possibility that these observations were caused by altered lymphoid environments, we generated BM chimeras consisting of 50% Ly5.1+ WT and 50% Ly5.2+ WASp\(^{-/-}\) B cells. Ca\(^{2+}\) flux and proliferation experiments using cells isolated from transplanted mice led to findings that mirrored the aforementioned results (Fig. 3, D and E).

WASp plays an important role in cytoskeletal rearrangement, leading us to hypothesize that a defect in BCR internalization might explain the observed increase in AR responsiveness. Although down-regulation in BCR surface expression was detected in WASp\(^{-/-}\) B cells after BCR stimulation, this decrease was much less pronounced over the first 10 min compared with WT cells (Fig. 3 C). Together, these data indicate that WASp\(^{-/-}\) B cells are hyper-responsive to BCR stimulation, possibly because of decreased receptor internalization.

CD4 T cell depletion reduces autoantibody production and prevents disease in WASp\(^{-/-}\) chimeras

We hypothesized that the presence of WT T cells was critical for the formation of GCs and IgG2b subclass CSR, and for development of systemic autoimmune disease in WASp\(^{-/-}\) chimeras. To test this hypothesis, we treated a new cohort of WT and WASp\(^{-/-}\) chimeras weekly with monoclonal CD4-depleting antibody (Fig. S4). Although WASp\(^{-/-}\) chimeras depleted of CD4 T cells still produced IgG anti-dsDNA antibodies, albeit at lower levels than in untreated WASp\(^{-/-}\) chimeras, CD4 depletion completely prevented IgG2c anti-dsDNA production (Fig. 4 A). In contrast, IgG3 autoantibodies were not eliminated by CD4 depletion (Fig. 4 A). In addition, although lower in titer than untreated WASp\(^{-/-}\) chimeras, IgG2b autoantibodies were significantly higher in CD4-depleted WASp\(^{-/-}\) chimeras than in WT chimeras (Fig. 4 A). As expected, WASp\(^{-/-}\) chimeras depleted of CD4 T cells did not exhibit an increase in GC phenotype (B220+ PNA+FAS+) splenocytes (Fig. 4 B) and lacked spontaneous GC formation in splenic sections (Fig. 4 C). Finally, CD4 depletion prevented the glomerular pathology and IgG2b/c and C3 deposition that were observed in untreated or isotype antibody-treated WASp\(^{-/-}\) chimeras (Fig. 4 D). These data support our hypothesis that WT T cells in WASp\(^{-/-}\) chimeras drive CSR and affinity maturation of autoreactive WASp\(^{-/-}\) B cells, leading to production of pathological autoantibodies and systemic autoimmune disease.

DISCUSSION

Autoimmunity is a hallmark of WAS, typically manifesting as humoral autoimmune disease in up to 70% of WAS patients (Sullivan et al., 1994; Dupuis-Girod et al., 2003). Additionally, a large number of patients develop systemic autoimmunity after stem cell transplantation, and this complication strongly correlates with mixed chimerism (Ozsahin et al., 2008). Here, we demonstrate that autoantibody production in WASp\(^{-/-}\) mice does not result from a lack of T cell-mediated immunosuppression. We next addressed whether WASp\(^{-/-}\) B cells might trigger autoimmunity using mixed BM chimeras where only B cells lacked expression of WASp. Our data indicate that WASp\(^{-/-}\) B cells play a primary role in driving autoimmunity; indicating that a single gene defect in B cells, yielding a modest increase in BCR and TLR signaling, is sufficient to trigger a cell-intrinsic loss in tolerance, culminating in pathogenic autoantibody production and lethal autoimmune disease in the setting of intact T cell function. We also show that B cell–intrinsic MyD88 signaling is essential for spontaneous GC formation, autoantibody production, and development of renal pathology.

Consistent with a B cell–intrinsic model, we show for the first time that WASp\(^{-/-}\) B cells are modestly hyperresponsive to both anti-IgM and TLR stimulation, as measured by Ca\(^{2+}\) flux, proliferative responses, and modulation of activation markers. Additionally, we show that WASp\(^{-/-}\) B cells exhibit decreased BCR internalization, possibly accounting for at least
Figure 3. WASp-/- B cells are mildly hyper-responsive and display reduced BCR internalization. (A) Left and middle panel, Ca²⁺ flux in FM B cells stimulated with 10 or 1 µg/ml anti-IgM. (right) slgM expression in WT versus WASp-/- FM B cells. Data are representative of 4 independent experiments (n = 8). (B) CFSE proliferation assay of sorted WT versus WASp-/- FM B cells on day 3 after stimulation (1 = 1 µg/ml; 10 = 10 µg/ml). Data are representative of 3 experiments (n = 10). (C) BCR internalization assay. WT and WASp-/- splenic B cells were incubated with biotinylated Fab', fragments to bind the BCR and chased for the indicated time points. Data are displayed as percentage of surface BCR relative to 0 time point. Data are representative of two independent experiments (n = 6 per experiment). (D and E) To assess the BCR signaling response in WT and WASp-/- B cells derived from the same environment, BM from WT (Ly5.1+) and WASp-/- (Ly5.2+) mice was mixed at a 50:50 ratio and transplanted into lethally irradiated MT recipient mice; recipients were sacrificed at 6–8 wk after transplant. (D) Ca²⁺ flux in stimulated FM B cells in the presence (top) or absence (bottom) of extracellular Ca²⁺ showing response in WT (Ly5.1+) versus WASp-/- (Ly5.2+) gated FM populations stimulated with 10 µg/ml anti-IgM. (right) Relative slgM expression in WT versus WASp-/- FM B cells. (E) Proliferation of sort-purified, WT (Ly5.1+) versus WASp-/- (Ly5.2+) FM B cells isolated from BM chimeras at day 3 after stimulation with the indicated mitogens. Data are representative of 2 independent experiments (n = 4 per experiment). FM B cells were sorted as CD19⁺CD24⁻CD21⁺ cells, as previously described (Meyer-Bahlburg et al., 2008).
a subset of these increased responses. Despite delayed BCR internalization, WASp−/− mice do not have increased surface IgM levels on naive B cells. This may be because delayed internalization does not affect steady-state surface IgM levels, or, alternatively, WASp−/− mice may have more autoreactive B cells in the preimmune repertoire, resulting in increased BCR engagement and subsequent down-regulation. Increased responsiveness to TLR ligands may also be caused by altered receptor processing, but this has not yet been tested. Contrary to our findings in B cells, multiple studies have shown decreased AR responsiveness in WASp−/− T cells. Although the precise mechanisms remain to be determined, the opposing effect of WASp deficiency in B versus T cell AR signals likely reflects differing roles for the actin cytoskeleton in initiating and sustaining such responses. Notably, our findings are consistent with previous data in WASp-interacting protein (WIP)–deficient mice (Antón et al., 2002). Although WIP−/− B cells exhibited increased proliferation and CD69 expression (WIP)–deficient mice (Antón et al., 2002). Although WIP−/− B cells exhibited increased proliferation and CD69 expression in response to BCR and TLR4 engagement, WIP−/− T cells failed to proliferate or produce IL-2 after TCR stimulation; these findings are consistent with the role for WIP in stabilizing WASp expression (Ramesh and Geha, 2009). In concert with our findings, autoimmune glomerulonephritis has also been described in WIP−/− mice (Curcio et al., 2007).

Importantly, despite being intrinsically autoreactive, our data clearly show that WASp−/− B cells alone are not sufficient to initiate severe autoimmune disease. WASp−/− mice develop anti-dsDNA autoantibodies, but, in contrast to WASp−/− chimeras, show minimal organ pathology and have normal lifespans. Strikingly, WASp−/− mice primarily generated IgG3 anti-dsDNA antibodies, as might be expected as a result of a T cell–independent process, whereas autoantibodies in WASp−/− chimeras were comprised of IgG2 isotypes, previously shown to be associated with C3 deposition and nephritis in SLE animal models (Ehlers et al., 2006). This suggests that in WASp−/− mice, WASp−/− T cells provided suboptimal cognate T cell help, an idea that is consistent with defective activation of WASp−/− T cells in response to CD3 ligation or antigen-specific target cells (Bouma et al., 2009). In contrast, WT T cells present in WASp−/− chimeras appear to be essential to drive CSR and affinity maturation of pathogenic autoantibodies. Consistent with this view, CD4 T cell depletion abrogated the generation of IgG2c anti-dsDNA antibodies, despite intact production of IgG3 autoantibodies. Consistent with our findings, CD4 T cell depletion or B cell–intrinsic MyD88-deficiency prevents disease development in WASp−/− chimeras. (A) ELISAs were used to measure dsDNA-specific total IgG, IgG3, IgG2b, and IgG2c serum antibodies (18 wk after transplant) in WASp−/− chimeras, WASp−/− chimeras treated weekly with CD4-depleting antibody (CD4 Depletion), and WASp−/− MyD88−/− chimeras (WASP−/− MyD88−/−). Data are normalized to values obtained from WT chimera controls run alongside each experimental group, and significance tests demonstrate whether experimental values are statistically greater than control values for each ELISA. Dotted line is at normalized value 1, representing autoantibody levels in WT chimera controls. (B) Percentage of splenic PNA+ FAS+ B cells in WT chimeras, WASp−/− chimeras, CD4-depleted WASp−/− chimeras and WASp−/− MyD88−/− chimeras (6 mo after transplant). (C) Immunofluorescent staining of splenic sections from WASp−/− chimeras (6 mo after transplant) to measure GC formation in WASp−/− chimeras, CD4-depleted WASp−/− chimeras, and WASp−/− MyD88−/− chimeras. Representative follicles (10× objective) are shown using B220 (red), CD3 (blue), and PNA (green). Bars, 100 µm. (D) Glomeruli of indicated chimeras were stained with the indicated reagents. PAS, Periodic acid-Schiff. Bars, 50 µm. *, P < 0.05; **, P < 0.005; ***, P < 0.0005. Isotype-treated WT and WASp−/− chimeras showed no differences from untreated animals, respectively, and therefore data from isotype-treated mice are not shown as a separate group. Data are representative of two independent experiments with WASp−/− MyD88−/− chimeras (n = 30 and n = 15), and one independent CD4-depletion experiment (n = 24).
and prevented formation of renal pathology. However, WASp−/− chimeras depleted of CD4 T cells still produced IgG2b anti–dsDNA antibodies, although at lower levels than in WASp−/− chimeras treated with isotype antibodies, indicating T cell–independent activation. In addition, CSR can explain some of the IgG2b autoantibodies in WASp−/− chimeras. The presence of IgG2b subclass autoantibodies in CD4-depleted chimeras, but not WASp−/− mice, suggests that hematopoietic cells other than CD4 T cells may provide activating signals that contribute to CSR, dependent on the expression of WASp. WASp−/− DCs have an impaired ability to prime T cells (Bouma et al., 2007), and may also lack the ability of WT DCs to promote B cell activation, possibly via impaired antigen presentation or secretion of soluble factors.

TLR signaling and MyD88 play a prominent role in B cell activation in various autoimmune models (Marshak-Rothstein and Rifkin, 2007), and DNA-specific B cells are capable of activation and antibody production in vitro after only BCR and TLR engagement (Viglianti et al., 2003; Fields et al., 2006). Therefore, we evaluated the contribution of TLR signaling in our model by generating chimeras lacking both WASp and MyD88 only in the B cell compartment. Deficiency of MyD88 prevented development of IgG anti–dsDNA antibodies, spontaneous GCs, and renal pathology, confirming its importance in the autoimmune disease observed in WASp−/− chimeras. In another study (Barr et al., 2009), antigen-specific IgG2c, but not IgG2b, IgG3, or IgG1, in response to T cell–dependent antigen immunization was shown to completely depend on B cell MyD88 signaling, possibly because of the failure of MyD88-deficient B cells to activate IFN-γ–producing effector T cells. In our model, the lack of any IgG DNA-specific antibodies in the absence of B cell MyD88 signals suggests that initial activation of DNA-specific B cells requires simultaneous BCR and TLR engagement, perhaps by cell death–derived nuclear autoantigens. Experiments are underway to determine whether specific TLRs, such as TLR9, are responsible for the effect of MyD88 deficiency. Additionally, based upon the requirement for MyD88 in TACI-dependent CSR, it will be of interest to determine the potential role for TACI engagement by BAFF or APRIL in this process (He et al., 2010).

In summary, we provide insight into the pathogenesis of autoimmunity in WASp−/− mice, suggesting that hyperresponsive B cells play a primary role in initiating lack of tolerance and producing anti-DNA autoantibodies. Several mouse models have been described in which alterations in B cell signaling molecules contribute to development of autoimmune disease (Cornall et al., 1998; Bolland and Ravetch, 2000; Grimaldi et al., 2005). In mice lacking the inhibitory receptor FcrRIB, development of autoimmunity also appears to be B cell intrinsic and MyD88/TLR9 dependent (Ehlers et al., 2006). Recent data on this model suggests this is primarily caused by failure of GC cell negative selection, and not a defect in selection of the preimmune repertoire (Tiller et al., 2010). Although further experimentation is required to define how increased antigen responsiveness in WASp−/− B cells first impacts BCR specificities within the mature repertoire, according to our model, DNA-reactive WASp−/− naive B cells are initially activated by combined BCR and TLR engagement, to which WASp−/− B cells are hyperresponsive. In WASp−/− chimeras, these activated, autoantigen-specific B cells then recruit T cell help, leading to GC formation and production of high-affinity, class-switched autoantibodies. This idea is consistent with recent evidence from models using transgenic BCRs in autoimmune-prone mice, suggesting that B cells can play a primary role in initiating systemic autoimmunity through dual BCR/TLR activation (Herlands et al., 2008). Although not directly evaluated here, we predict that these combined events are exaggerated by, and may require, increased levels of BAFF in recipient μMT mice; an idea that is consistent with the role for T cell–independent, MyD88–dependent generation of autoantibodies in BAFF transgenic mice (Groom et al., 2007). Notably, elevated BAFF is also observed in WAS (and other immune-deficient) patients undergoing stem cell transplantation, and may similarly amplify alterations in B cell tolerance in that setting (unpublished data). Ultimately, autoantibody–containing IgG2b/c immune complexes deposit in tissues such as kidney glomeruli, initiating end-organ pathology via their preferential binding to activating IgG Fc receptors (Nimmerjahn and Ravetch, 2005).

Our findings appear to provide a compelling mechanistic explanation for clinical observations wherein a large proportion of WAS transplant recipients with mixed chimerism develop severe, humoral autoimmunity, and suggest that these events should be considered in the design of future strategies for stem cell transplantation and viral-based gene replacement in WAS. Moreover, our data lend strong support to an emerging model (Shlomchik, 2009) whereby BCR/TLR–mediated activation of autoreactive B cells can function as the primary driver leading to subsequent break in T cell tolerance and systemic autoimmunity.

MATERIALS AND METHODS

Mice. Ly5.1+ and Ly5.2+ C57BL/6, μMT, WASp−/− (F10 on a C57BL/6 background), and MyD88−/− mice were bred and maintained in the specific pathogen–free animal facility of Seattle Children’s Research Institute (Seattle, WA) and handled according to Institutional Animal Care and Use Committee approved protocols.

Reagents and antibodies. Anti–mouse antibodies used in this study include the following: CD24 (M1/69), CD21 (7G6), B220 (RA3-6B2), IgD (11-26C.2A8), CD11 (9M1/70), IgD− (AMS 9.1), CD3e (145 2C11), and CD4 (RM4-5) (all from BD); BP1 (FG5-5), CD25 (PC61), CD62L (M-14), CD11c (N418), Gr-1 (RB6-8C5), and Foxp3 (FJK-16S) (all from EMD Bioscience); CD23 (B3B4) (Invitrogen); IgG (Jackson ImmunoResearch Laboratories). Purified polyclonal rabbit anti–IgG3, anti–IgG2b, anti–IgG2a, anti–IgG1, anti–IgM, and anti–IgD were produced in rabbits (Jackson ImmunoResearch Laboratories). F(ab')2 fragments of goat anti–IgG– conjugated to Cy5 (Jackson ImmunoResearch Laboratories) and Texas Red (Jackson ImmunoResearch Laboratories) were used. Mouse anti–IgE (clone BP3), mouse anti–IgG2b, mouse anti–IgG2c, rat anti–IgG1, and rat anti–IgG2a (Discoveris Biotechnology) were purchased. Mouse anti–IgG2a, mouse anti–IgG2c, mouse anti–IgM, rat anti–IgG2a, and mouse anti–IgG3 (Southern Biotechnology) were purchased. Anti–IgG1, goat anti–IgG3, mouse anti–IgM, rat anti–IgG2b, and mouse anti–IgG2c were purchased from Jackson ImmunoResearch Laboratories. Mouse anti–IgG2a (Invitrogen) was conjugated with Texas Red (Jackson ImmunoResearch Laboratories). Purified polyclonal rabbit anti–WASP was provided by Dr. Hans Ochs (University of Washington, Seattle).

Flow cytometry and cell sorting. As previously described (Meyering and van der Velden et al., 2006b), single-cell suspensions from BM, peripheral blood, and spleen were incubated with fluorescently labeled antibodies, and data were
collected on a FACSCalibur or LSR II (BD) and analyzed using FlowJo software (Tree Star). Intracellular WASp staining, cell sorting, and gating strategies were also performed as previously described (Meyer-Bahlburg et al., 2008a,b). Sort purities were >90% in all studies.

**BM transplantation.** BM was harvested from W4Sp−/− or WT mice, and plasma cells were depleted using anti-CD138 microbeads (Miltenyi Biotec). BM from W4Sp−/− or WT mice was mixed at a 20:80 ratio with µMT BM, and 5 × 10^6 total BM cells in PBS were injected i.v. into lethally irradiated µMT mice. W4Sp−/− or CS7BL/6 Ly5.1+ BM cells were mixed equally and injected into lethally irradiated µMT mice.

**Immunofluorescence of spleen sections.** Mouse spleens were embedded in OCT compound and frozen over dry ice and isopropanol alcohol. 5-µm sections were cut on a cryostat, mounted on Superfrost plus slides, dried, fixed in −20°C acetone for 20 min, dried at room temperature, and stored at −80°C. For immunofluorescence staining, sections were rehydrated in staining buffer (PBS, 1% goat serum, 1% BSA, and 0.1% Tween-20), washed, and stained for 30 min at room temperature with B220-PE, PNA-FITC, and CD3-Alexa Fluor 647. Slides were washed and fixed with mounting media, and images were acquired using a DM6000B microscope, DFL300 FX camera, and Application Suite Advanced Fluorescence software (all from Leica).

**In vitro cell activation studies.** In vitro activation studies were performed as previously described (Meyer-Bahlburg et al., 2008a; Andrews and Rawlings, 2009). Ca^2+ flux was measured by flow cytometry using splenic B cells incubated with Indo-1 (Invitrogen), surface stained, and then washed. Cells were incubated with fluorescein-conjugated antibodies against mouse IgG, IgM, and IgA, acetone-fixed frozen sections were air-dried, washed in PBS, and stained with Hematoxylin and eosin. Renal histopathology and urine analysis.

**Renal histopathology and urine analysis.** Kidney tissue was fixed in neutral buffered formalin, processed, and embedded in paraffin according to standard practices. Tissue sections were stained with hematoxyl and eosin (H&E), periodic acid-Schiff and silver methenamine. Portions of kidney in OCT were snap-frozen, and frozen sections were used for immunofluorescence and oil red O staining. Portions of formalin-fixed tissue were processed for EM as previously described (Taneda et al., 2001). For immunofluorescence, acetone-fixed frozen sections were air-dried, washed in PBS, and incubated with fluorescein-conjugated antibodies against mouse IgG, IgM, IgA, and complement C3 from Cappel Pharmaceuticals; IgG3, IgG2b, and IgG2c from Southern Biotechnology; and MAC2 from Cedarlane. After washing, slides were mounted with Vectashield mounting media (Vector) and viewed using a Nikon Optiphot-2. Images were acquired using a Canon Eos SD Mark II and the corresponding product software, and Adobe Photoshop was used for adjustments. Alb/Cr ratios were determined according to the manufacturer’s instructions using Albuvell M and Creatinine Companion kits (Excocell).

**BCR internalization assay.** Internalization assay was performed as previously described (Sharma et al., 2009). Anti-CD19 was used for gating splenic B cells.

**Antigen microarrays.** Microarray studies were performed with nitrocellulose-coated slides, as previously described (Silverman et al., 2008). Background correction used a MATLAB script, and the mean values for replicate spots were determined with JMP 7.0 software. Cluster analysis diagrams from comparisons of replicate arrays, after processing with mononuclear IgM or sera, were generated with Cluster 3.0 (Stanford University) and Java TreeView (rana.lbl.gov/EisenSoftware.htm). Background levels were confirmed based on replicate slides developed without sera. In these studies, a level of 600 digital fluorescence intensity units was set as a threshold for significant reactivity, which was the mean background ± 3 SD.

**T cell depletion.** Mice were treated weekly with i.p. injection of 250 µg anti-CD4 (GK1.5) or isotype control (rat IgG2b) antibody (UCSF Antibody Core) beginning 5 wk after transplant.

**Statistical evaluation.** P-values were calculated using the two-tailed Student’s t test. For analysis of survival, Kaplan-Meier analyses were used.

**Online supplemental material.** Fig. S1 shows functional analysis of W4Sp−/− T reg cells and relative chimerism of splenic populations in BM chimeras. Fig. S2 shows ELISAs testing MDA-LDL reactivity of sera samples. Fig. S3 further explores the hyperresponsiveness in W4Sp−/− B cells. Fig. S4 demonstrates efficacy of long-term CD4 depletion. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20110200/DC1.

The authors thank Dr. Hans Ochs (University of Washington) for providing anti-WASP antibodies and members of the Rawlings laboratory for helpful discussions. This work was supported by National Institutes of Health grants HD037091 and AI01163 (to D.J. Rawlings); KD037162 (to C.E. Alpers); AI40305 and AI46637 (to G.J. Silverman); and ST22AR01207-32 (for S.W. Jackson); an ACR Research Education Foundation grant and Arthritis Foundation IRG grant (to G.J. Silverman); a PDTIC Fellowship Award (to S. Becker-Herman), and a Cancer Research Institute Pre-doctoral Training Grant (to M.A. Schwartz).

The authors have no conflicting financial interests.
