Atypical and classical memory B cells produce *Plasmodium falciparum* neutralizing antibodies

Matthias F. Muellenbeck,1 Beatrix Ueberheide,3 Borko Amulic,2 Alexandra Epp,1 David Fenyo,4 Christian E. Busse,1 Meral Esen,5,6 Michael Theisen,7,8 Benjamin Mordmüller,5,6 and Hedda Wardemann1

Antibodies can protect from *Plasmodium falciparum* (*Pf*) infection and clinical malaria disease. However, in the absence of constant reexposure, serum immunoglobulin (Ig) levels rapidly decline and full protection from clinical symptoms is lost, suggesting that B cell memory is functionally impaired. We show at the single cell level that natural *Pf* infection induces the development of classical memory B cells (CM) and atypical memory B cells (AtM) that produce broadly neutralizing antibodies against blood stage *Pf* parasites. CM and AtM contribute to anti-*Pf* serum IgG production, but only AtM show signs of active antibody secretion. AtM and CM were also different in their IgG gene repertoire, suggesting that they develop from different precursors. The findings provide direct evidence that natural *Pf* infection leads to the development of protective memory B cell antibody responses and suggest that constant immune activation rather than impaired memory function leads to the accumulation of AtM in malaria. Understanding the memory B cell response to natural *Pf* infection may be key to the development of a malaria vaccine that induces long-lived protection.

Malaria caused by *Plasmodium falciparum* (*Pf*) infection is a leading cause of morbidity and mortality primarily in children in sub-Saharan Africa (Murray et al., 2012). Protective immunity to control clinical disease caused by parasite growth in red blood cells (RBCs) takes years to develop and requires repeated infections (Garnham, 1949). Human serum IgG antibodies can protect from blood stage parasitism and malaria symptoms as demonstrated by historic passive transfer studies (Cohen et al., 1961). However, in the absence of constant reexposure, serum IgG levels rapidly decline and protection from malaria wanes, suggesting that protective humoral memory is not efficiently formed or is functionally impaired (Struik and Riley, 2004; Dorfman et al., 2005; Langhorne et al., 2008). Indeed, repeated *Pf* infection is associated with the accumulation of circulating atypical memory B cells (AtM) that are characterized by expression of the inhibitory Fc-receptor-like-4 (FcRL4; Weiss et al., 2009, 2010, 2011). FcRL4-positive memory B cells have originally been described in tonsils of healthy individuals (Elhradt et al., 2005, 2008). Circulating FcRL4-positive AtM also present in chronic HIV infection, where they show signs of functional exhaustion and hyporesponsiveness after in vitro stimulation suggesting that their memory B cell function is impaired (Moir et al., 2008). The role of AtM in immunity to malaria is speculative and it is unclear whether AtM contribute to the production of protective serum antibodies in vivo. To address these questions, we performed a molecular and functional characterization of the anti-*Pf* classical memory B cells (CM) and AtM response in immune adult donors from a malaria endemic area in Gabon.

area. By single cell antibody cloning and mass spectrometry we show that CM and AtM express Pf-neutralizing antibodies and contribute to serum IgG production in vivo.

RESULTS
PF-reactive CM and AtM in malaria immune adults
To determine the molecular and functional antibody characteristics of anti-Pf memory B cells, we set out to generate a panel of recombinant monoclonal antibodies from circulating IgG-positive CM and AtM of three asymptomatic semi-immune adults (MP036, MP070, and MP071; Table S1). The individuals were selected from a cohort of 67 healthy subjects with neutralizing serum IgG activity against asexual blood stage parasites from a highly endemic area in Gabon (Fig. 1 A; Dal-Bianco et al., 2007). All donors presented with a high frequency of circulating CD27-CD21- AtM that showed increased FcRL4 and CD19 expression as well as lower IgG surface expression compared with CM (Fig. 1, B and C).

The Pf genome is highly complex, and only a few antigens out of the >5,000 possible protein products have been associated with humoral protection against asexual blood stage parasites (Gardner et al., 2002; Fowkes et al., 2010). We therefore focused our analysis on two Pf antigens, merozoite surface protein 3 (MSP3) and glutamate-rich protein (GLURP), that have been described to induce serum IgG responses that are associated with protection from clinical malaria (Meraldi et al., 2004; Singh et al., 2009; Fowkes et al., 2010). Specifically, we studied the anti-Pf IgG B cell response to the vaccine candidate GMZ2, a fusion protein of the immune-dominant GLURP R0 nonrepeat region that is expressed at all parasitic life cycle stages in the human host, and the conserved domain of MSP3 that is critically involved in RBC invasion (de Stricker et al., 2000; Rodríguez et al., 2005; Esen et al., 2009). All individuals, including the selected donors, had high titers of serum IgG antibodies against GMZ2, MSP3, and GLURP and showed GMZ2 reactivity in CM and AtM (Fig. 1, D–F; and not depicted). In summary, the selected donors showed representative anti-Pf serum IgG and memory B cell responses as well as high frequencies of circulating AtM.

Figure 1. Memory B cell sorting. (A) Relative 3D7Luc neutralizing activity of 100 µg/ml purified serum IgG from study participants in comparison to polyclonal serum IgG preparations from nonimmune controls (0% neutralization) and 50 mM chloroquine (100% neutralization, dashed gray line). Dots represent individual samples. Selected donors for antibody cloning are indicated. (B) Gating strategy for the flow cytometric isolation of CM and AtM. Representative plots from MP070 are shown. (C) Frequency of circulating CM and AtM. (D) IgG GMZ2 reactivity in serum as measured by ELISA. The dotted line shows a Pf-naive control serum. (E) Flow cytometric analysis of GMZ2-reactive CM and AtM in peripheral blood from MP036, MP070, and MP071 compared with a malaria naive donor. (F) Frequency of circulating GMZ2-reactive CM and AtM in all donors as determined in E. Red bars indicate arithmetic mean.
Ig gene repertoire of Pf-reactive CM and AtM
To generate recombinant monoclonal antibodies, the Ig gene variable regions of single isolated GMZ2-reactive CM and AtM from MP036, MP070, and MP071 were cloned into expression vectors (Tiller et al., 2008). Ig gene sequence analysis demonstrated that the memory IgG response was highly diverse (Tables S2–S4). No major differences in the IGH and IGK or IGL gene segment usage or IGH CDR3 features between CM and AtM were observed (Fig. 2 D; mean ± SEM: AtM, IGH 28.1 ± 8.1, IGK 20.6 ± 9.1, and IGL 20.1 ± 1.7; CM, 24.5 ± 7.7, IGK 17.2 ± 9.5, and IGL 20.1 ± 1.5). IGH and IGK/IGL gene sequence alignments showed that clonally expanded B cells with identical Ig gene rearrangements were observed within both compartments. However clonally related CM and AtM were not detected in any of the three donors (Fig. 2 E). Statistical models based on the observed distributions of clonal relatives predict that if CM and AtM were directly derived from a shared ancestor, the likelihood of a random absence of shared clusters would be <0.1% on average for each of the donors. Thus, we conclude that CM and AtM show differences in their somatic hypermutation load and lack signs of clonal relationship, suggesting that the two populations may originate from different precursors.

Pf MSP3 and GLURP antigen specificity of CM and AtM antibodies
To determine whether anti-Pf CM and AtM show differences in their antigen reactivity, we expressed 236 recombinant monoclonal CM and AtM antibodies and performed ELISA (Fig. 3, A, C, and D; and Tables S2–S4). On average, 91 ± 7% of antibodies showed reactivity with the sort antigen GMZ2 (Fig. 3 A). For individual binders, reactivity with Pf merozoites was confirmed by fluorescence microscopy with infected RBCs (iRBCs; Fig. 3 B). We further discriminated between MSP3 and GLURP antigen reactivity by ELISA (Fig. 3, C and D). MSP3-specific antibodies were more frequent than GLURP-specific antibodies in both memory B cell compartments (Fig. 3 E; mean ± SEM: MSP3, 70.3 ± 12.7% for CM and 67.3 ± 16.0% for AtM; GLURP, 17.0 ± 11.3% for CM and 11.3 ± 10.0% for AtM). However, even in the presence of high concentrations of
The frequency of polyreactive antibodies was significantly higher in the AtM than in the CM compartment (Fig. 4B; mean ± SEM: 64.3 ± 6.2% vs. 38.7 ± 8.4%; P = 0.004), and polyreactive antibodies were enriched in the MSP3+GLURP compartment (Fig. 4C). However, independently of the level of polyreactivity, anti-Pf antibodies, but not non-Pf reactive control antibodies, bound preferentially to iRBCs and not to non-iRBCs (Fig. 4D). Thus, we conclude that CM and AtM express polyreactive and nonpolyreactive anti-Pf antibodies, and polyreactive antibodies are enriched in the AtM compartment.

CM and AtM antibodies neutralize Pf RBC invasion

Next, we tested if antibodies from Pf-reactive memory B cells neutralize asexual blood stage parasites (Fig. 5). Using an

BSA, ~12.7 ± 7.7% of CM and 22.7 ± 9.0% of AtM antibodies bound both antigens at similar levels (Fig. 3E and not depicted). In summary, the majority of GMZ2-reactive CM and AtM antibodies were MSP3 specific, but a fraction of the antibodies showed reactivity with GLURP or MSP3+GLURP.

Polyreactive antibodies are enriched in the anti-Pf AtM compartment

Dual reactivity with MSP3 and GLURP may suggest that the antibodies lacked Pf specificity and were polyreactive. To determine the degree of polyreactivity, we tested our collection of recombinant monoclonal antibodies for reactivity with diverse non-Pf antigens: bacterial LPS, human insulin, and double-stranded DNA (dsDNA; Fig. 4A and Tables S2–S4).

The frequency of polyreactive antibodies was significantly higher in the AtM than in the CM compartment (Fig. 4B; mean ± SEM: 64.3 ± 6.2% vs. 38.7 ± 8.4%; P = 0.004), and polyreactive antibodies were enriched in the MSP3+GLURP compartment (Fig. 4C). However, independently of the level of polyreactivity, anti-Pf antibodies, but not non-Pf reactive control antibodies, bound preferentially to iRBCs and not to non-iRBCs (Fig. 4D). Thus, we conclude that CM and AtM express polyreactive and nonpolyreactive anti-Pf antibodies, and polyreactive antibodies are enriched in the AtM compartment.
Thus, IgG memory B cells expressing neutralizing antibodies against genetically diverse asexual blood stage parasites develop in response to Pf infection.

CM and AtM contribute to the production of anti-Pf serum IgG

CM can contribute indirectly to the production of serum IgG antibodies after differentiation into antibody-secreting cells (Bernasconi et al., 2002), but whether AtM produce serum Ig in vivo is not known. To determine if the IgG antibodies that we cloned from CM and AtM could be detected in serum, we analyzed Fab2 fragments derived from protein G–purified MSP3- and GLURP-reactive serum IgG of donor MP036 by mass spectrometry (Fig. 6 A; Scheid et al., 2011). We then compared the amino acid sequences obtained from the mass spectrometric analysis to the Ig sequence database of the recombinant monoclonal CM and AtM antibodies from the same donor (Fig. 6 B and Fig. S1). We obtained amino acid sequence hits that mapped to the CM and AtM database but not to the international human protein index database, suggesting that both populations contribute to anti-Pf serum IgG production.

By PCR, we were able to detect secretory IgG transcripts in AtM but not in CM, suggesting that AtM actively secrete antibodies in vivo and contribute directly to the humoral anti-Pf response (Fig. 6 C). Indeed, the IgG subclass

Figure 4. CM and AtM antibody polyreactivity. (A) ELISA reactivity with dsDNA, LPS, and insulin of CM and AtM antibodies from MP071. Non-polyreactive (green line; mGO53) and low (red line; JB40) and high (black dashed line, ED38) polyreactive control antibodies are shown. Dashed blue line indicates reactivity threshold. (B) Frequency of polyreactive CM and AtM antibodies from MP036, MP070, and MP071. (C) Symbols indicate antibody polyreactivity as the mean area under curve (AUC) for reactivity with dsDNA, insulin, and LPS. Horizontal lines indicate mean levels of antibody polyreactivity in all three donors. Error bars indicate SEM, and P-values were calculated using the ANOVA test. (D) Histograms show reactivity with noninfected Hoechst-negative RBCs (red line) and Hoechst-positive Pf-infected iRBCs (blue line) for representative polyreactive and nonpolyreactive anti-MSP3, anti-GLURP, and anti-MSP3+GLURP antibodies as determined by flow cytometry. Polyreactive (ED38) and nonpolyreactive (mGO53) control antibodies from malaria naive controls are shown. Gray areas show the iRBC reactivity of the non Pf-reactive isotype control antibody mGO53 in each plot. Data shown are representative for two independent experiments.
reactivity, but in vivo Fc-mediated effector functions may add to parasite neutralization (Bouharoun-Tayoun et al., 1990). Humoral immunity to MSP3 and GLURP has been associated with protection from malaria, and we observed neutralization for anti-MSP3 as well as anti-GLURP memory antibodies (Singh et al., 2009; Fowkes et al., 2010). Anti-MSP3 antibodies were more frequent than anti-GLURP antibodies, suggesting that MSP3 may be more efficient in inducing IgG memory B cell responses than GLURP. However, it cannot be excluded that the use of GMZ2 as bait for the isolation of anti-
Pf memory B cells may enrich for MSP3-specific B cells. Differences in the nature of individual 
Pf antigens may account for differences in the induction of long-term humoral memory responses that have also been observed for viral and vaccine antigens (Taylor et al., 1996; Dorfman et al., 2005; Tönsgren et al., 2006; Amanna et al., 2007; Akpogheneta et al., 2008; Amanna and Slifka, 2010).

The relatively low level of antigenic variation in the MSP3 and GLURP peptides analyzed in this study may facilitate the generation of broadly inhibitory memory B cells (Manske et al., 2012). Whether neutralizing memory B cell antibodies are generated at similar frequencies to other antigens remains to be determined. Acquisition of protective humoral immunity to 
Pf may, however, also be associated with qualitative differences in the neutralizing activity of these antibodies. Thus, future studies

DISCUSSION

In summary, we show that immunity to malaria is associated with the development of memory B cells that express 
Pf neutralizing antibodies and contribute to serum IgG production. In mice and humans, stable memory B cell responses against 
Plasmodium antigens have been detected, but whether the antibodies produced by memory B cells were neutralizing was not known (Wipasa et al., 2010; Nogaro et al., 2011; Ndungu et al., 2012). We found that the majority of memory B cell antibodies showed 
Pf neutralizing activity, including antibodies with broad neutralizing activity against genetically diverse 
Pf strains. Neutralization in our in vitro assays was a direct effect of antigen reactivity, but in vivo Fc-mediated effector functions may add to parasite neutralization (Bouharoun-Tayoun et al., 1990).

Humoral immunity to MSP3 and GLURP has been associated with protection from malaria, and we observed neutralization for anti-MSP3 as well as anti-GLURP memory antibodies (Singh et al., 2009; Fowkes et al., 2010). Anti-MSP3 antibodies were more frequent than anti-GLURP antibodies, suggesting that MSP3 may be more efficient in inducing IgG memory B cell responses than GLURP. However, it cannot be excluded that the use of GMZ2 as bait for the isolation of anti-
Pf memory B cells may enrich for MSP3-specific B cells. Differences in the nature of individual 
Pf antigens may account for differences in the induction of long-term humoral memory responses that have also been observed for viral and vaccine antigens (Taylor et al., 1996; Dorfman et al., 2005; Tönsgren et al., 2006; Amanna et al., 2007; Akpogheneta et al., 2008; Amanna and Slifka, 2010).

The relatively low level of antigenic variation in the MSP3 and GLURP peptides analyzed in this study may facilitate the generation of broadly inhibitory memory B cells (Manske et al., 2012). Whether neutralizing memory B cell antibodies are generated at similar frequencies to other antigens remains to be determined. Acquisition of protective humoral immunity to 
Pf may, however, also be associated with qualitative differences in the neutralizing activity of these antibodies. Thus, future studies

Figure 5. 
Pf merozoite neutralizing activity of CM and AtM antibodies. (A) 3D7 transgenic parasite growth in the presence of individual antibodies (black lines; MP070) or the indicated controls. (B) Relative 3D7 neutralizing activity of GMZ2-reactive antibodies at 6.4 µg/ml. Horizontal lines indicate mean neutralizing activity. (C) 3D7 neutralizing activity of individual MSP3, GLURP, and polyreactive CM and AtM antibodies as in B. Black bars indicate geometric mean. (D) Relative 
Pf 3D7, HB3 (Honduras), DD2 (Thailand), and IT4 (Brazil) neutralizing activity of GMZ2-reactive antibodies at 100 µg/ml compared with chloroquine (100%). Parasites were detected using SYBR green. Data shown are representative of at least two independent experiments.
IgM memory B cells, but their role in Plasmodium infection is not clear (Ndungu et al., 2009; Nduati et al., 2010; Reynaud et al., 2012). A thorough characterization of the quality and quantity of the human anti-Pf IgM memory B cell antibody response may help to elucidate the relative contribution of IgM versus IgG B cell memory to Pf infection in humans.

A large fraction of the recombinant monoclonal antibodies will have to assess whether protection from clinical disease is not only associated with changes in the magnitude and overall breadth of the response but also with changes in the frequency of memory B cells that produce Pf neutralizing antibodies (Courtin et al., 2009; Nogaro et al., 2011). In addition, the role of IgM-expressing memory B cells in the response to Pf remains to be determined. Studies in mice suggest that long-term memory is predominately the role of IgM memory B cells, but their role in Plasmodium infection is not clear (Ndungu et al., 2009; Nduati et al., 2010; Reynaud et al., 2012). A thorough characterization of the quality and quantity of the human anti-Pf IgM memory B cell antibody response may help to elucidate the relative contribution of IgM versus IgG B cell memory to Pf in humans.

A large fraction of the recombinant monoclonal antibodies were polyreactive and such antibodies were enriched in the

Figure 6. CM and AtM contribution to anti-Pf serum IgG. (A) Representative MS/MS spectra. Observed b-type fragment ions (containing the N terminus), y-type fragment ions (containing the C terminus), and loss of water (*) are indicated. Ions corresponding to the loss of water are labeled. Observed backbone cleavages are indicated ( for b-type ions, for y-type ions). Data shown are representative of at least three independent experiments on two different instruments. (B) IgH amino acid sequences of CM and AtM antibodies. Framework regions (FWR) and complementarity determining regions (CDR) are indicated. Blue stars indicate somatic point mutations. Mass spectrometric peptides with identical amino acid sequence are indicated in red. (C) RT-PCR amplicons of secretory and membrane IgG transcripts from the indicated B cell subpopulations. Data shown are representative of at least two independent experiments. (D) Serum IgG subclass distribution in donors from the Lambaréné area. (E) IgG subclass distribution as determined by IGH gene transcript sequence analysis. n indicates the number of tested sera. Error bars indicate SD.
AtM compartment. However, polyreactive antibodies specifically recognized iRBCs and not non-iRBCs, suggesting that the level of binding to non-Pf antigens was relatively low compared with the affinity for Pf. Polyreactivity is a frequent feature of antibody responses to viral infections and has been shown to play a protective role against HIV, but whether such promiscuous antibodies are also beneficial in the immune response against Pf remains to be determined (Haynes et al., 2005; Mouquet et al., 2010; Mouquet and Nussenzweig, 2012).

AtM showed signs of activation, proliferation, and active antibody secretion, suggesting that their development in response to Pf is associated with differentiation into antibody-secreting cells rather than with a defect in B cell memory as previously proposed for HIV (Ehrhardt et al., 2008; Moir et al., 2010). Immunity to Pf is not sterilizing, and the frequent antigenic stimulation by repeated infections may induce Pf-reactive antigen-experienced B cells to develop into antibody-secreting cells and to acquire an AtM phenotype, a process which may be facilitated by the polyreactive nature of the antigen receptors expressed by AtM.

The relative contribution of AtM to the anti-Pf serum IgG response cannot be assessed, and although we demonstrate that AtM secrete Pf neutralizing antibodies, it remains to be determined whether AtM fulfill true memory functions or if they simply represent a population of circulating short-lived antibody-secreting cells. The fact that AtM were almost negative for the plasma cell marker CD138, but showed signs of proliferative activity and expressed surface IgG as well as MHC II and various activation markers, supports the notion that AtM resemble plasma blasts rather than long-lived plasma cells that were displaced from the bone marrow by recent infection (Ndungu et al., 2009).

The antibody repertoire of AtM was distinct from CM, suggesting that the two populations may develop from different precursors. A deeper analysis of the Ig gene repertoire of anti-Pf CM and AtM in comparison to tissue resident memory B cells and long-lived plasma cells may help to determine the origin of circulating AtM (Ehrhardt et al., 2005, 2008; Moir et al., 2008).

The memory B cell antibodies cloned in this study are fully human and may therefore be used in experimental human malaria infection to determine their protective efficacy against Pf asexual blood stages (Roestenberg et al., 2012). Understanding the protective properties as well as the limitations...
in the memory B cell antibody response to \( Pf \) is crucial for developing vaccination strategies that elicit neutralizing antibodies to protect from clinical malaria.

**MATERIALS AND METHODS**

**Study participants.** Healthy adults (age 19–57 yr, mean 33 ± 10 yr) were recruited in the Lambaréné area (Gabon, Africa; Table S1). Peripheral blood samples were obtained after signed informed consent during dry season. None of the donors had previously participated in any malaria vaccine study. Parasitemia was assessed by microscopy, PCR (nested), and rapid diagnostic test (NOW ICT Malaria Test; Binax Inc.). Ethical approval was obtained from the Comité d’Ethique Régional Indépendant de Lambaréné (No. 17/10).

**Flow cytometry.** Peripheral blood mononuclear cells were purified using Percoll gradient density centrifugation. Flow cytometric analyses were performed on an LSR II instrument (BD). IgG memory B cells were isolated using an ARIA II flow cytometric cell sorter (BD). \( Pf \) GLURP, MSP3, and GMZ2 antigens were produced and purified as previously described (Thesen et al., 2004). GMZ2 was chemically coupled to Alexa Fluor 647 according to the manufacturer’s instructions (Life Technologies). For use in flow cytometry, the following mouse antibodies were used: anti-human CD19-PE-Cy7, anti-human IgG-APC-H7, anti-human CD27-FTTC, anti-human CD38-V450, anti-human CD86-FTTC, anti-human CD138-FTTC (all from BD), anti-human CD21-PE, anti-human CD21-APC, anti-human CD24-biotin, anti-human CD27-biotin, anti-human CD84-biotin, anti-human HLA-DR-APC (all from eBioscience), anti-human Ki-67-PE (BioLegend), and anti-human FcRL4-biotin (gift of G.H. Ehrhardt and M. Cooper, Emory University School of Medicine Atlanta, GA). Streptavidin-QD605 (Life Technologies) was used to detect biotin-conjugated primary antibodies. 7-AAD (Life Technologies) was used in all experiments to exclude dead cells. For intracellular staining with anti-human Ki-67-PE (BioLegend) and 7-AAD (Invitrogen), PBMCs were permabilized using Fix & Perm solution (BD) according to the manufacturer’s instructions.

**Single-cell sorting and antibody cloning.** Single-cell sorting and antibody cloning was performed as previously described with the following modifications: cells were sorted into 384–well plates and volumes of RT-PCR reactions were scaled by a factor of 0.25 (Tiller et al., 2008; Schedl et al., 2011). In brief, single cells were isolated using flow cytometric cell sorting. cDNA was generated in the original 384-well sort plates. Ig gene transcripts were amplified by nested RT-PCR, and sequenced and cloned into IgGl human heavy and Igk or Igk light chain expression vectors, respectively. For in vitro antibody production, HEK293T cells were cotransfected with Ig heavy and matching Ig light chain plasmids. Recombinant monoclonal antibodies were purified from culture supernatant under sterile conditions using protein G beads. Antibodies were eluted from protein G beads using 0.1 M glycine, pH 3, and neutralized in 10× PBS for use in ELISA and neutralization assays. IgG concentrations were determined by ELISA.

**ELISA.** ELISAs were performed as previously described (Tiller et al., 2008). In brief, antigens or goat anti-human IgG (Dianova) were coated overnight at 4°C. For \( Pf \) antigen ELISAs, GMZ2, MSP3, or GLURP were coated at a concentration of 10 ng/well and plates were blocked with PBS-B (1× PBS, 0.05% vol/vol Tween-20, and 0.01% wt/vol EDTA) supplemented with 1% BSA for 1 h before incubation with recombinant monoclonal antibodies for 2 h at room temperature. For polyclonality ELISAs, antigens were coated at with 10 µg/ml diDNA or LPS or 5 µg/ml insulin and plates were blocked with PBS-B for 1 h. For IgG concentration ELISAs of purified serum IgG or recombinant monoclonal antibodies, human IgG1k from plasma of myeloma patients (Sigma-Aldrich) was used as standard. Bound recombinant monoclonal antibodies were detected using anti-human IgG-HRP antibody (Dianova). Anti-human IgG-HRP antibodies were detected using anti–human IgG-HRP antibody (Dianova). Anti–human IgG-HRP antibodies were detected using one-step ABTS substrate (Roche). Area-under-curve (AUC) values were calculated using PRISM (GraphPad Software). Antibodies were considered polyclonar when they recognized at least two out of the three structurally different antigens: diDNA, insulin, and LPS. Internal high (ED38) and low (BJ40) positive and negative (mGSS3) control antibodies were used in all assays to set thresholds for polyclonality (Wardemann et al., 2003; Meffre et al., 2004; Tiller et al., 2008).

**Pf cultures and inhibition assays.** Parasites were cultured under standard conditions. In brief, \( Pf \) clone 3D7 and isolates DD2, HB3, and IT2 were cultured at 5% hematocrit in RPMI 1640 supplemented with 0.08 g/liter hypoxanthine (Sigma-Aldrich), 25 mM Heps, 0.5% Albumin II (Life Technologies), 0.25% sodium bicarbonate, and 0.01 mg/ml gentamicin (Sigma-Aldrich). All cultures were kept at 37°C under 90% nitrogen, 5% oxygen, and 5% carbon dioxide. 3D7inf cultures were supplemented with 40 ng/ml pyrimethamine to ensure transgene expression. Neutralization assays were performed with synchronized late stage 3D7inf or 3D7, DD2, and HB3 cultures at a starting parasitemia of 0.2 or 0.5%, respectively. Parasites were cultured in duplicates in the presence of recombinant monoclonal antibodies or protein G purified serum IgG. Uninfected cultures, chemical inhibitors (chloroquine and artemisinin at 50 mM), whole serum (10%), and mGSS3 (non–\( Pf \) reactive recombinant monoclonal antibody) were used as internal controls. 3D7inf growth was measured after merozoite release and reinvasion after 24 h by quantifying luciferase activity using Bright-Glo Luciferase substrate (Promega). Arbitrary luminescence units were measured on a VICTOR Light reader (1420 Luminescence Counter, PerkinElmer). Growth of 3D7, HB3, IT4, and DD2 cultures was assessed after 48 h using SYBR green (Smilkstein et al., 2004). Fluorescence was measured on a Fluoroscan Ascent reader (Thermo Fisher Scientific).

**Indirect immunofluorescence assay.** Late stage percoll-sorbitol purified 3D7 iRBCs were allowed to settle on poly-L-lysine-coated glass slides. Cells were fixed with 4% paraformaldehyde/0.0075% glutaraldehyde before permeabilization with 0.2% Triton X-100. Blocking with BSA (3%) was performed before incubation with individual human recombinant monoclonal antibodies (10 ng/ml). Bound antibodies were detected using Cy3-conjugated mouse anti-human IgG-Fc (Jackson Immunoresearch Laboratories). Hoechst 33342 was used to stain parasite DNA (Life Technologies). Images were acquired on a microscope (DMR; Leica) with an HCX PL FLUOTAR 100×/1.3 objective using a digital camera (DXM 1200F; Nikon). ACT-1 (version 2.7; Nikon) was used as acquisition software.

**Secretory and membrane IgG PCR.** CM, AtM, naive B cells (CD19+IgM+IgD+), and plasmablasts (CD19+CD27+CD38+IgG+) were bulk isolated by flow cytometric cell sorting. Secretory and membrane IgG transcripts were amplified by RT-PCR using an IGH gene forward primer mur and 5’-TCTCCTGGCGCAGCCCGAGACG-3’ (secretory) or 5’-GTC-CACACGCCCCGTACCCTCC-3’ (membrane as reverse primer, respectively. Amplification was performed using HotStar Taq (QIAGEN) at 94°C for 15 min, 50°C (94°C for 30 s, 68°C for 45 s, and 72°C for 30 s), 72°C for 10 min for secretory and 94°C for 15 min, 50°C (94°C for 30 s, 65°C for 45 s, and 72°C for 2 min), and 72°C for 10 min for membrane IgG transcripts. PCR products were separated on 2% agarose gels.

**Mass spectrometry.** Mass spectrometric analyses were performed as previously described (Schedl et al., 2011). In brief, Fab2 fragments were generated from protein G–Sepharose purified serum IgG. MSP3 and GLURP reactive Fab2 fragments were isolated using HIS-tagged MSP3 and GLURP, respectively, and anti-HIS Dynabeads (Life Technology). MSP3 and GLURP reactive Fab2 fragments were reduced with diithiothreitol, alkylated using iodoacetamide, resolved by 1D gel electrophoresis on a 4–12% NuPAGE Novex Bis–Tris gel (Invitrogen), and stained with Coomassie Blue (Thermo Fisher Scientific). Fab2 fragments were excised from the gel and digested using 200 ng trypsin (Promega). The resulting peptides were isolated using reverse phase resin (POROS 20 R2; Applied Biosystems) and eluted using 40% acetonitrile in 0.5% acetic acid. Acetonitrile was removed using a speedvac (Thermo Fisher Scientific). The peptides were resuspended in 0.5% acetic acid and injected onto a PicoFrit column (New Objective) using a Proxeon nLC 1000 (Thermo Fisher Scientific). The HPLC column was interfaced to either an Orbitrap Velos or a Q Exactive Orbitrap mass spectrometer (Thermo Fisher Scientific). The peptides were eluted using the following gradient: 0–5% B in 5 min, 40% B in 125 min, 60% B in 150 min, 100% B in 165 min (A = 0.1 M acetic acid, B = 90% acetonitrile in 0.1% acetic acid). Fluorescence units were measured on a VICTOR light reader (1420 Luminescence Counter, PerkinElmer). Growth of 3D7, HB3, IT4, and DD2 cultures was assessed after 48 h using SYBR green (Smilkstein et al., 2004). Fluorescence was measured on a Fluoroscan Ascent reader (Thermo Fisher Scientific).
peptides (only charge states >1 and <5) were isolated with a 2D window, target data-dependent mode. For analysis on the Orbitrap Velos, a full scan was followed by a 20 MS/MS scans on the 20 most abundant ions in that full scan. The peptides (only charge states >1 and <5) were isolated with a 2D window, target window of 1e4 ions, dissociated via CAD (normalized collision energy = 35, activation Q = 0.25, activation time = 30 ms) and mass analyzed in the LTQ. For analysis on the Q Exactive Orbitrap, a full scan (resolution 70,000 at m/z 200) was followed by a 10 MS/MS scan on the 10 most abundant ions from the preceding full scan. The peptides (only charge states >1 and <5) were isolated with a 2D window, target window of 2e4 ions, dissociated with normalized collision energy of 27, and mass analyzed with a resolution of 17,500 (at m/z 200). For either instrument, the ions selected for MS/MS were set on an exclusion list for 30 s. The resulting MS/MS spectra were searched against the Human IPI and in-house-specific IgG database using Xtandem. Peptide hits corresponding to GM22-reactive CM or AtM IgG sequences were manually confirmed.

SNP analysis and stochastic calculation. SNP analysis was performed using next-generation sequencing data of 222 Pf isolates supplied by the MalariaGen Genomic Epidemiology Network (Manske et al., 2012; Data Release 1.0). The mean number of clusters of clonally related cells was determined by maximum likelihood estimations using a multivariate hypergeometric distribution model and the singlet/doublet frequencies observed over all donors/populations while assuming a uniform size of the individual clusters. If CM and AtM cells differed in their surface phenotype but were derived from the same population, the likelihood of not observing any shared clusters within an individual donor can be approximated as a (1 − c/2)^c, where c is the calculated overall number of clusters, the number of a unique clusters sampled from the first population, and b the number of unique samplings from the second population.

Online supplemental material. Fig. S1 provides peptide data for the mass spectrometry analysis of purified anti-GM22 serum IgG from MP036. Table S1 provides clinical information on blood samples from MP036, MP070, and MP071. Tables S2, S3, and S4 provide Ig gene and antibody reactivity information for anti-merozoite antibodies from MP036, MP070, and MP071, respectively. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20121970/DC1.

We are indebted to all study participants. We thank S. Issifou, A.A. Adegnika, S.T. Agerandj, B. Leil, D.R.M. Mouzouna, J. Kamer, L. Laurens, and S. Pinto for their support in Lambaréné. F. Tuller, K. Tetteh, S. Dunyo, D.E. Lanar, M. Pinder, and A. Zychlinsky for critical comments to the manuscript. K. Deitsch for parasite strains and K. Matuschewski for technical support. We thank K. Deitsch for parasite strains and K. Matuschewski for technical support in Lambaréné. F. Tuller, C. Kreschel, and C. Achten provided excellent parasitological aspects of the work in Lambaréné were supported by the European and the International Max Planck Research School for Infectious Diseases (IMPRS-IDI).
