Interventional strategies to treat atherosclerosis, such as transluminal angioplasty and stent implantation, often cause vascular injury. This leads to intimal hyperplasia (IH) formation that induces inflammatory and fibroproliferative processes and ultimately restenosis. We show that phosphoinositide 3-kinase γ (PI3Kγ) is a key player in IH formation and is a valid therapeutic target in its prevention/treatment. PI3Kγ-deficient mice and mice expressing catalytically inactive PI3Kγ (PI3Kγ KD) showed reduced arterial occlusion and accumulation of monocytes and T cells around sites of vascular lesion. The transfer of PI3Kγ KD CD4+ T cells into Rag2-deficient mice greatly reduced vascular occlusion compared with WT cells, clearly demonstrating the involvement of PI3Kγ in CD4+ T cells during IH formation. In addition we found that IH is associated with increased levels of Th1 and Th17 cytokines. A specific decrease in the Th1 response was observed in the absence of PI3Kγ activity, leading to decreased CXCL10 and RANTES production by smooth muscle cells. Finally, we show that treatment with the PI3Kγ inhibitor AS-605240 is sufficient to decrease IH in both mouse and rat models, reinforcing the therapeutic potential of PI3Kγ inhibition. Altogether, these findings demonstrate a new role for PI3Kγ activity in Th1-controlled IH development.

Vascular disease is a significant cause of morbidity and mortality in developed countries and results from vascular injury. Among pathological phenomena that take place in the arterial wall, intimal hyperplasia (IH) usually precedes atherosclerosis and is a complication of transluminal angioplasty and stent implantation which are interventional strategies used in the treatment of atherosclerosis (Bennett, 2003). IH is an exaggerated healing process of the vessel wall defined as the formation of a multicellular layer within the arterial lumen and characterized by inflammatory and fibroproliferative responses. Injury of the endothelium leads to the recruitment of activated platelets and leukocytes (Costa and Simon, 2005), followed by abnormal proliferation and migration of medial smooth muscle cells (SMCs) that subsequently undergo a dedifferentiation process. This results in fibrocellular intimal thickening and a reduction in blood flow,
which can have dramatic consequences especially if a coronary artery is affected.

Many studies have focused on the proliferative component of IH as the target for treatment (Lindner et al., 1993; Schwartz et al., 1998; Dzau, 2003). Drug-eluting stents (DESs) coated with antiproliferative agents have been shown to have beneficial effects on the development of IH (Bikkina and Koneru, 2011); however, the lack of specificity of the DES is thought to cause side effects such as thrombosis (Lagerqvist et al., 2007). Moreover, some patients have presented with genetic resistance to either the eluted drugs or the polymer used to recover the stent (Dangas et al., 2010). These issues highlight the need to identify new therapeutic targets for IH.

Recently, inflammation has emerged as a key process at the heart of IH development, revealing a whole new array of possible targets for the control of neointimal formation. Various studies have shown an association between in-stent restenosis and inflammation in patients. For example, the fracture of a metallic stent placed in the femoral artery was shown to correlate with both a greater recruitment of inflammatory cells around the stent and a subsequent increase in the severity of restenosis (Farb et al., 2002). In response to injury, leukocytes are recruited to the arterial wall (Boehm et al., 2004; Marx et al., 2011) and an acute inflammatory response has been shown to initiate the development of IH. In agreement with this, intimal thickening can be reduced by inhibition of leukocyte recruitment through modulation of the MCP-1–CCR2 signaling pathway in animal models of arterial injury (Horvath et al., 2002; Grassia et al., 2009). The sequence of events immediately after arterial injury has recently been characterized and involves the recruitment of inflammatory cells and the expression of proinflammatory cytokines (Kovacic et al., 2010); the subsequent increase in the concentrations of growth factors and cytokines then activates SMC to migrate and proliferate (Marx et al., 2011). Therefore, modulating the acute immune response may be an alternative strategy to inhibit IH, thus avoiding the nonspecific side effects of anti-fibroliprotective agents.

In this context, class IB phosphoinositide 3-kinase γ (PI3Kγ) is of particular interest in the study of inflammatory and cardiovascular pathologies. PI3Kγ is largely expressed in inflammatory cells but has also been identified in cells of the cardiovascular system, particularly endothelial cells and SMC. The recruitment of this kinase downstream of G protein–coupled receptors accounts for its implication in the chemotactic migration of leukocytes because these receptors are largely responsible for binding chemokines and directing cell migration in leukocytes. PI3Kγ-deficient mice (PI3Kγ KO) have been used to demonstrate that PI3Kγ is involved in numerous biological functions of immune cells such as monocyte/macrophage recruitment to inflammatory sites (Hirsch et al., 2000), thymocyte development (Sasaki et al., 2000), T lymphocyte activation (Alcázar et al., 2007), and mastocyte degranulation (Laffargue et al., 2002). In arterial studies, both treatment with a specific PI3K inhibitor and the specific deletion of PI3Kγ in the immune system in LDLR−/− mice reduced atherosclerotic lesions by preventing inflammatory processes occurring in the vascular wall (Fougerat et al., 2008). Moreover, the generation of a mouse model expressing a catalytically inactive form of PI3Kγ (PI3Kγ kinase dead, KD) allowed the analysis of PI3K–dependent from PI3K–independent functions in cardiac cells (Patrucco et al., 2004; Perino et al., 2011). This useful model mimics the effects of a pharmacological inhibitor of the kinase while preserving any eventual off-target side effects. Finally, PI3Kγ has recently been identified as a mediator of vascular SMC migration (Fougerat et al., 2012). Together, these studies suggest that PI3Kγ could play an important role in the development of IH.

Here, using genetic and pharmacological approaches, we have identified PI3Kγ as an essential mediator of acute inflammatory vascular events during neointima formation. Lymphocyte-deficient mice and BM chimeras were used to demonstrate that, after vascular injury, the activity of PI3Kγ clearly controls CD4+ T cell–induced IH. We found that Th1 and Th17 cytokines were produced during IH progression and that the absence of PI3Kγ activity specifically modulated the Th1 cytokine profile, which had an impact on the SMC inflammatory response. Finally, we show that a short period of treatment with a PI3K inhibitor decreased IH development in two different but complementary animal models: a mouse femoral artery mechanical injury model and a rat carotid artery balloon injury model. These data open the perspective of investigating PI3Kγ as a target for the prevention of arterial damage in interventional cardiology.

Femoral arteries from WT (n = 13), PI3Kγ KD (n = 9), and PI3Kγ KO mice (n = 11) were mechanically injured and analyzed 28 d after injury. IEL and EEL, respectively, indicate areas defined by the internal elastic laminae and external elastic laminae. Data are expressed as mean ± SEM for each group and are representative of two independent experiments, n = 9–13 mice per group. *, P < 0.05; **, P < 0.01; ***, P < 0.001 versus WT controls. Data were analyzed with a Mann-Whitney test.
Genetic targeting of PI3Kγ activity leads to decreased neointimal formation after vascular injury

To investigate the functional role of PI3Kγ in response to arterial injury, we induced a mechanical injury of the femoral artery in WT, PI3Kγ KD, and PI3Kγ KO mice and analyzed neointimal formation 28 d later. Morphometric analysis of injured femoral arteries showed a significant decrease in intimal area, accompanied by a significant increase in lumen area in PI3Kγ KD and PI3Kγ KO mice compared with WT controls (Table 1). Normalization with the medial area showed that the mean intima/media ratio in PI3Kγ KD and PI3Kγ KO mice was reduced by 72 and 76%, respectively, compared with WT mice (intima/media ratios: WT, 2.37 ± 0.29 vs. PI3Kγ KD, 0.67 ± 0.16, P = 0.0002; WT vs. PI3Kγ KO, 0.58 ± 0.12, P < 0.0001; Fig. 1 A). For all groups the intima/media ratio was calculated from the same vessel segment to avoid neo-intimal variability in the distance from the ligation point. At each distance, the intima/media ratio was significantly lower in PI3Kγ KD and PI3Kγ KO mice compared with WT controls (Fig. 1 B). Histological analysis of the injured arteries (Fig. 1 C) showed a larger neointima in WT arteries compared with PI3Kγ KD and PI3Kγ KO mice.
with PI3Kγ KD and PI3Kγ KO vessels after Masson Trichrome staining (Fig. 1 C, top). Most neointimal cells expressed α-smooth muscle actin (Fig. 1 C, middle), suggesting an increased proliferation of SMC within the lesion. Interestingly, anti-CD31 immunostaining of endothelial cells indicated an incomplete endothelial coverage in WT mice, whereas it was more complete in PI3K KD and PI3K KO animals (Fig. 1 C, bottom), suggesting that the absence of PI3Kγ activity had improved endothelial healing in this model. These data demonstrate an important role for PI3Kγ in the development of IH after mechanical injury of femoral arteries. Moreover, the deletion of the whole enzyme or its catalytic activity shows similar responses, thus suggesting a kinase-dependent effect in the development of IH.

**PI3Kγ kinase activity in BM-derived cells is necessary for IH development**

PI3Kγ inhibition has an antinflammatory effect on atherosclerosis (Fougerat et al., 2008) and the activity of PI3Kγ is important for SMC migration (Fougerat et al., 2012). We therefore sought to compare the roles of PI3Kγ activity in immune cells versus nonimmune cells in the development of IH. For this purpose, we generated BM chimeras by transplanting BM from PI3K KD donors into WT recipients and vice versa. Controls were PI3K KD mice who received PI3K KD BM (BM KD→KD) and WT mice who received WT BM (BM WT→WT). 4 wk after BM transplantation, analysis of chimerism showed complete engraftment of donor BM in recipients (unpublished data). After engraftment, the femoral arteries of chimeric mice were injured, and then lesion sizes were quantified 28 d later. In BM KD→WT chimeras, the intima/media ratio was decreased by 52% compared with BM WT→WT chimeras (Fig. 2 A), whereas a WT immune system on a PI3K KD background (BM WT→KD) reestablished the IH rate to that of a WT background (Fig. 2 B), demonstrating the importance of immune PI3Kγ activity in IH. BM KD→KD chimeras had a similar intima/media ratio as BM KD→WT mice. Moreover, the use of a pharmacological inhibitor of PI3Kγ in primary vascular SMC, even at high doses, did not impact on SMC proliferation (Fig. 2 C), further ruling out direct effect of PI3Kγ in SMC during IH. Our data indicate that the absence of catalytically active PI3Kγ in BM-derived cells alone is sufficient to prevent fibroproliferative mechanism at the same rate as the ubiquitous inactivation of the kinase.

**PI3Kγ activity is responsible for early inflammation and the sequential recruitment of monocytes/macrophages and T cells around the lesion site**

Given the important functional involvement of PI3Kγ in the immune system, we then compared the local inflammatory profile in WT and PI3Kγ KD arteries 6 h after injury. The expression of three main proinflammatory mediators (IL-6, IL-1β, and TNF) was assessed by quantitative PCR. IL-6, IL-1β, and TNF mRNA expression was significantly decreased in the absence of PI3Kγ activity (Fig. 3 A).

To dissect the cellular mechanisms involved in PI3Kγ-mediated IH, we characterized the immune cells that had...
infiltrated the vessel walls around the injured site in WT mice at different time points after injury. Monocytes/macrophages (F4/80+ cells) accumulated around the vessels 3 d after the injury, whereas few lymphocytes (CD3+ cells) were observed (not depicted). At days 8 (not depicted) and 28 (Fig. 3 B), F4/80 staining became more pronounced, whereas CD3-positive cells became more numerous than at day 3. The accumulation of T cells was observed in the perivascular tissue and in the neointima. Interestingly, PI3Kγ KD artery sections showed less monocytes/macrophages and a reduction in T cell recruitment around the lesion site compared with WT arteries, suggesting a role for PI3Kγ in the recruitment of both cell types (Fig. 3 B).

**PI3Kγ activity drives CD4+ T cell–induced IH development**
To explore the role played by lymphocytes in the development of IH, we performed arterial injury in Rag2 KO mice that are deficient in mature T and B lymphocytes. Consistent with previous findings (Boehm et al., 2004), Rag2 KO mice exhibited a 53% lower intima/media ratio compared with WT mice (Fig. 4 A), suggesting that lymphocytes promote IH development. Reconstitution with WT but not PI3Kγ KD T cells was able to restore IH (Fig. 4 B), demonstrating the central function of PI3Kγ activity in T cells during IH development. In this Rag2 KO mouse model, monocytes/macrophages with active PI3Kγ were recruited at the same rate whether reconstituted with WT or PI3Kγ KD donors (Rag2 KO + WT T cells; Rag2 KO + PI3Kγ KD T cells). 28 d later, the femoral arteries of mice were mechanically injured and analyzed 28 d after injury. Representative sections show injured femoral arteries stained with Masson Trichrome and histogram shows quantitative analysis of the intima/media ratio of indicated mice. (B and C) Rag2 KO recipient mice were reconstituted with T lymphocytes from WT or PI3Kγ KD donors [Rag2 KO + WT T cells; Rag2 KO + PI3Kγ KD T cells]. 28 d later, the femoral arteries of mice were mechanically injured and analyzed 28 d after injury. (B and C) Representative sections show injured femoral arteries stained with Masson Trichrome and histogram shows quantitative analysis of the intima/media ratio of indicated mice. (B) Representative photomicrographs show sections of injured femoral arteries stained with Masson Trichrome and histogram shows quantitative analysis of monocyte/macrophage content after F4/80 staining or T lymphocyte content after CD3 staining. Bars, 100 µm. Data are expressed as mean ± SEM and are representative of two independent experiments. n = 5–15 mice per group. *, P < 0.05. Data were analyzed with Mann-Whitney test.
T cells that had infiltrated the periadventitial tissue were mainly CD4+ T cells (Fig. 5A), whereas CD8+ cells were undetectable. In agreement, injection of WT CD4+ T cells into Rag2 KO mice increased IH compared with Rag2 KO mice that did not receive CD4+ cells, showing that the CD4+ subpopulation is involved in the development of this pathology (Fig. 5 B). Importantly, PI3Kγ KD CD4+ cells failed to increase IH, demonstrating that this kinase plays a key role in the action of CD4+ cells (Fig. 5 B).

**Specific modulation of the Th1 response in the absence of PI3Kγ activity reduces the SMC inflammatory response**

The cytokine profile of CD4+ T cells plays a central role in orchestrating the outcome of an immune response. To specifically define which types of cytokine were present in injured femoral arteries, we used an ex vivo system. Injured and uninjured femoral artery rings from WT and PI3Kγ KD mice were incubated with a PMA/Ionomycin cocktail. After 72 h, the release of IFN-γ, IL-4, and IL-17 was measured, classically reflecting the Th1, Th2, and Th17 subpopulations, respectively. Interestingly, IFN-γ and IL-17 were detected at high levels in injured arteries, whereas poor levels of IL-4 were produced, indicating that Th1- and Th17-related cytokines are those predominantly involved in IH (Fig. 6 A). In addition, in the absence of PI3Kγ activity, IL-4 and IL-17 levels were not modified, whereas IFN-γ levels were dramatically decreased, demonstrating that PI3Kγ activity specifically modulates Th1 cytokines during IH progression (Fig. 6 A). We also analyzed the intracytoplasmic content of IFN-γ and IL-17 by CD4+ T cells collected from inguinal LN (ILNs) and showed an increase in IFN-γ after injury. As we observed in injured arteries, the absence of PI3Kγ activity led to a dramatic decrease in IFN-γ, confirming the importance of PI3Kγ in the Th1 response (Fig. 6 B). Surprisingly, we did not observe any difference concerning the IL-17 production by CD4+ T cells originating from injured mice compared with uninjured mice. This contrasts with our results in injured arteries and suggests that a population other than CD4+ T cells is responsible for IL-17 production (not depicted). Interestingly, we also found that CXCL10 and RANTES, both involved in leukocyte recruitment, were secreted at high levels in injured femoral arteries compared with uninjured arteries and that their levels were dramatically lower in the absence of PI3Kγ, indicating that PI3Kγ was responsible for their secretion at the site of injury (Fig. 6 C). Based on these results, we hypothesized that the inhibition of CXCL10 and RANTES secretion by SMC depended on Th1 cytokines. To test this hypothesis, we stimulated cultured SMC with different doses of IFN-γ and measured the synthesis of CXCL10 and RANTES mRNA. Results show that the genetic expression of these chemokines was increased in response to IFN-γ stimulation in a dose-dependent manner (Fig. 6 D). Of note, the PI3Kγ inhibitor did not modify IFN-γ-induced CXCL10 or RANTES synthesis even at high doses, excluding the involvement of SMC PI3Kγ (Fig. 6 E). Altogether, these data indicate that PI3Kγ activity has an impact on CXCL10 and RANTES secretion by SMC through modulation of IFN-γ secretion.

**Short-term inhibition of PI3Kγ protects against trauma induced by vascular injury in mouse and rat IH models**

To validate the possibility of a PI3Kγ inhibitor being used for the prevention of restenosis, we evaluated the efficiency of a selective PI3Kγ inhibitor in two models of IH induction in rodents. Mice and rats were submitted to a short period of treatment with the PI3Kγ-selective inhibitor AS-605240 at a dose of 10 mg/kg/d for 2 d before and for the first 10 d after surgery (Fig. 7 A). 28 d after mechanical injury of the femoral artery lesion, mice treated with AS-605240 showed a dramatic decrease (43% reduction) in the intima/media ratio compared with
hematopoietic cells and, albeit to a lesser extent, by cells of the cardiovascular system. Thus this kinase is an interesting protein in the field of cardiovascular disease research. Our previous work has identified PI3K as an essential player in arterial wall inflammatory processes during atherosclerosis (Fougerat et al., 2008) and in SMC migration in vitro (Fougerat et al., 2012). In the present study, we have evaluated the suitability of PI3K as a target for therapeutic intervention in the prevention of vascular damage after angioplasty. For this study, we used the femoral artery endovascular injury model that is characterized by neointima formation as a consequence of an excessive accumulation of SMC and deposition of extracellular matrix in the intimal layer of the vessel wall, a response which reflects the “in-stent” restenosis observed in humans (Lindner et al., 1993; Roque et al., 2000). Using this model, we show that pharmacological inhibition of PI3K, genetic deletion of PI3K, or expression of catalytically inactive PI3K all lead placebo-treated mice (Fig. 7 B). The level of inhibition caused by the treatment was comparable to that obtained in PI3K KD mice, indicating that a short period of PI3K inactivation was sufficient to decrease IH formation. Moreover, AS-605240 treatment did not induce additional inhibition of IH in PI3K KD mice (Fig. 7 C), indicating that the observed effects were specifically due to PI3K inhibition. To firmly establish the therapeutic benefit of PI3K inhibition, we then used a rat carotid balloon injury model. 14 d after balloon injury, rats treated with AS-605240 showed a 59% reduction in the intima/media ratio compared with placebo-treated animals (Fig. 7 D). Altogether, these data demonstrate that a short period of PI3K inhibition is sufficient to protect against IH in two different rodent models.

**DISCUSSION**

In contrast to class IA PI3Ks that are ubiquitously expressed, PI3K acts via G protein–coupled receptor signaling and presents an original expression profile. PI3K is expressed by hematopoietic cells and, albeit to a lesser extent, by cells of the cardiovascular system. Thus this kinase is an interesting protein in the field of cardiovascular disease research. Our previous work has identified PI3K as an essential player in arterial wall inflammatory processes during atherosclerosis (Fougerat et al., 2008) and in SMC migration in vitro (Fougerat et al., 2012). In the present study, we have evaluated the suitability of PI3K as a target for therapeutic intervention in the prevention of vascular damage after angioplasty. For this study, we used the femoral artery endovascular injury model that is characterized by neointima formation as a consequence of an excessive accumulation of SMC and deposition of extracellular matrix in the intimal layer of the vessel wall, a response which reflects the “in-stent” restenosis observed in humans (Lindner et al., 1993; Roque et al., 2000). Using this model, we show that pharmacological inhibition of PI3K, genetic deletion of PI3K, or expression of catalytically inactive PI3K all lead
A short-term pharmacological inhibition of PI3Kγ is sufficient to prevent IH. (A) Schematic representation of the experimental protocol used to pharmacologically inactivate PI3Kγ in mouse and rat models of IH. Animals were injected daily with vehicle or the selective PI3Kγ inhibitor AS-605240 (10 mg/kg) from 2 d before until 10 d after arterial injury. At day 0, mice underwent femoral artery mechanical injury, whereas rats were submitted to carotid artery balloon injury. Histological analysis of injured artery cross sections was performed 28 d after injury in mice, and 14 d after injury in rats. (B) Representative cross sections show femoral arteries of placebo- or AS-605240–treated WT mice stained with Masson Trichrome. Histogram shows quantitative analysis of the intima/media ratio in indicated mice. (C) Representative cross sections show femoral arteries of placebo- or AS-605240–treated PI3Kγ KD mice stained with Masson Trichrome. Histogram shows quantitative analysis of the intima/media ratio in indicated mice. (D) Representative cross sections show carotid arteries of placebo or AS-605240 treated Sprague Dawley (SD) rats stained with Masson Trichrome. Histogram shows quantitative analysis of the intima/media ratio in indicated rats. Bars: (B and C) 100 µm; (D) 400 µm. Data are expressed as mean ± SEM and are representative of two independent experiments, n = 7–10 mice per group, for B and C; and of one experiment, n = 8 rats per group, for D. **, P < 0.01. Data were analyzed with a Mann-Whitney test.

To a dramatic decrease in IH without any modification of medial thickness. These data indicate that PI3Kγ activity is not involved in arterial remodeling but plays a role in neointima formation. To evaluate endothelial coverage in this model, we performed an immunostaining of endothelial cells in injured arteries of mice from different genotypes. In the literature, little quantitative data is currently available about reendothelialization rate after mechanical femoral artery injury in the mouse (Tanaka et al., 2008). Here, we show with anti-CD31 staining 28 d after mechanical injury an incomplete endothelial coverage in WT mouse. Interestingly, reendothelialization seems improved in the absence of PI3Kγ or its activity. These data indicate that disruption of PI3Kγ activity leads to a decrease of IH without interfering with a correct reendothelialization. Nevertheless, additional investigation, including a quantitative approach of reendothelialization, needs to be done to better characterize the impact of absence of PI3Kγ in arterial healing.

Several lines of evidence strongly support a role for inflammation in the initiation of IH, and different inflammatory biomarkers have been linked to its progression. For example, regulation of NF-κB, a transcription factor involved in the production of many inflammatory immune mediators, induces a decrease in IH that is associated with reduced IL-6 expression (Niida et al., 2012). Reducing IL-1β levels by inhibiting its maturation in a pig model of in-stent restenosis also decreases neointimal size (Gyöngyösi et al., 2003). Moreover, suppression of TNF and IFN-γ in a synergistic manner in the BM attenuates IH (Murayama et al., 2008). Consistent with these data, we found a strong up-regulation of mRNAs encoding IL-6, TNF, and IL-1β very early after lesion induction. Interestingly, mRNA synthesis of these cytokines was inhibited by 65% in the absence of PI3Kγ activity, suggesting a function for PI3Kγ in acute inflammatory processes. The use of chimeric mice that specifically express PI3Kγ in hematopoietic cells demonstrates that its activity in immune cells alone is sufficient to induce IH. The sequential recruitment of immune cells after vascular injury is still ill-defined. Roque et al. (2000) identified neutrophils adhering to the luminal side within 24 h after mechanical femoral artery injury. Boehm et al. (2004) reported the presence of macrophages both 1 and 2 wk after endovascular mechanical injury in periadventitial tissue. They observed T lymphocytes in this area at the same time points. Our study provides new information on both the timing and the cell types involved in the development of IH. We have found that over the first 3 d after injury, monocytes/macrophages are the predominant cells present around the vessel. Then, T lymphocytes progressively accumulate in the perivascular tissue and can be detected at day 28. The exact function of T cells in the development of IH is controversial in the literature. Whereas Boehm et al. (2004) and Kovacic et al. (2010) reported that T cells are involved in the inflammatory processes of injured arterial walls leading to IH, Dimayuga et al. (2011) demonstrated that lymphocytes were protective against IH. This discrepancy regarding the role of T cells in vascular injury remains unclear, but perhaps the choice of injury model could explain the differences observed. Boehm et al. (2004) used an endovascular model of injury, whereas the other studies used a perivascular injury model, which involves placing a cuff around the artery. In agreement with this, a study performed by Tanaka et al. (2003)
clearly pinpointed the dominance of BM cell recruitment to the media and neointima after mechanical injury of the femoral artery when compared with cuff placement or ligation. The endovascular model would appear to be a better model for studying restenosis, as it is well established that lesions induced by bare metal stents are responsible for the first inflammatory events leading to IH (Toutouzas et al., 2004). The same discrepancy is found regarding the role of T cells in IH induced in the rat. Hansson et al. (1991) demonstrated that mu/mu rats developed more IH, indicating that T cells inhibit IH in rats. In contrast, there is some evidence suggesting a deleterious function of T cells in IH induced in the rat (George et al., 2001; Yoshimura et al., 2001). In the mouse, CD4+ and CD8+ T cells subpopulations seem to play opposite roles: CD4+ T cells seem to play a deleterious effect in a model of periadventitial injury (Dimayuga et al., 2013), whereas CD8+ T cells protect from IH formation (Dimayuga et al., 2013). Thus, it is possible that the apparent discrepancy observed in rat models could be related to a functional difference between CD4+ and CD8+ T cell subsets in IH development.

In our model, reconstitution of Rag2 KO mice with WT T cells restored the development of the disease, whereas PI3Kγ KO T cells did not, clearly indicating a role for T cells in IH and the importance of PI3Kγ in this cell type. The role of PI3Kγ in the maturation of thymocytes has been well studied, but its function in T cells has not yet been clearly established (Rodriguez-Borland et al., 2003). In vitro data have shown that the absence of PI3Kγ leads to decreased IL-2 and IFN-γ secretion in T cells stimulated by anti-CD3 antibodies, suggesting a role for PI3Kγ in Th1 polarization (Sasaki et al., 2000); however, in vivo data from a model of colitis induced by dextran sodium sulfate indicated that cytokines reflecting Th1 polarization are increased (van Dop et al., 2010). In a model of antigen-induced rheumatoid arthritis, Gruen et al. (2010) did not observe modifications in the production of Th1, Th2, or Th17 cytokines that could be dependent on PI3Kγ. The role of PI3Kγ in Th polarization is difficult to investigate, mostly because the number of T cells at the lesion site is modified in the absence of the kinase. One of the most important findings of our study is illustrated by the fact that the absence of PI3Kγ activity in T cells is sufficient to prevent IH despite a normal recruitment of immune cells (in Rag2 KO mice reconstituted with PI3Kγ KD T cells), clearly demonstrating a functional role for PI3Kγ in T cells in the development of the disease. Analysis of the cytokines present in injured arteries allowed us to identify a predominant Th1/Th17 phenotype, illustrated by high levels of IFN-γ and IL-17 and little IL-4. IL-17 is produced at high levels in injured artery explants in the presence as well as in the absence of PI3Kγ activity, indicating that cells expressing IL-17 infiltrate injured arteries during IH development independently of PI3Kγ. Moreover, these results indicated that PI3Kγ was not involved in the Th17 responses after vascular injury. In contrast, IFN-γ production was strongly inhibited in the absence of PI3Kγ activity, highlighting the importance of Th1 cells in IH. Moreover, analysis of intracytoplasmic production of IFN-γ in CD4+ T cells collected from ILNs confirms the specific involvement of PI3Kγ in Th1 response. Surprisingly, we did not observe any difference concerning the IL-17 production by CD4+ T cells originating from injured mice compared with uninjured mice. This contrasts with our results in injured arteries and suggest that a population other than CD4+ T cells is responsible for IL-17 secretion. In this regard, IL-17-producing cells other than CD4+ T cells have been described such as CD8+ αβ T cells (Kondo et al., 2009), γδ T cells (O’Brien et al., 2009), LTi-like innate lymphoid cells (Takatori et al., 2009), NK T cells (Rachitskaya et al., 2008), CD3+ invariant natural killer cells (Michel et al., 2007), and B cells (Schlegel et al., 2013). In addition, it is now widely accepted that diverse innate myeloid immune cells, such as monocytes and macrophages (Fujino et al., 2003), neutrophils (Hoshino et al., 2008), and mast cells (Lin et al., 2011), can produce IL-17. Regarding the number of monocytes/macrophages accumulated in the adventitia after arterial injury, we cannot exclude the possibility that, in injured arteries, these cells are able to secrete IL-17. Further experiments need to be done to better investigate the cell type involved in IL-17 secretion after arterial lesion. Together, these data are in agreement with our observation showing that PI3Kγ inhibition specifically modifies the Th1 T cell response in IH.

In the literature, the role of IFN-γ on SMC proliferation is controversial. Wang et al. (2007) demonstrated that increased expression of IFN-γ-induced SMC proliferation and intimal expansion in mouse. In contrast, Hansson and Holm (1991) and Castronuovo et al. (1995) demonstrated that injection of IFN-γ into rat decreased IH after balloon injury. All of these studies used a model overexpressing IFN-γ (by adenovirus or directly by injection of IFN-γ). We believe that the discrepancy between these findings could be due to the dose of IFN-γ effectively received by the SMC. Indeed, there are several pieces of evidence demonstrating that, depending on the dose, IFN-γ can activate or inhibit smooth cell proliferation (Shimokado et al., 1994). Using the reverse approach, Murayama et al. (2008) demonstrated that suppression of TNF and IFN-γ in a synergistic manner in the BM attenuated IH, suggesting that endogenous IFN-γ is involved in IH development. Interestingly, the transcriptomic analysis of atherosclerotic specimens and blood cells of patients with restenosis have been analyzed and indicated that IFN-γ signaling is activated in neointimal SMC (Zohlnhöfer et al., 2001), suggesting a common involvement of Th1 cells in human restenosis.

Few studies have reported the role of Th17 cells in IH. IL-17 and IFN-γ are produced concomitantly by human coronary infiltrating T cells during atherogenesis and act synergistically on vascular SMC to induce proinflammatory mediators such as CXCL10 and RANTES secretion (Eid et al., 2009). Our hypothesis was that similar mechanisms could exist after vascular injury and that PI3Kγ, by modulating IFN-γ and not IL-17, could participate in the modulation of the SMC response. We then investigated CXCL10 and RANTES secretion in injured arteries and found that both of these chemokines are highly expressed in injured arteries, whereas...
their levels are dramatically decreased in the absence of PI3K\(\gamma\) activity. Moreover, our in vitro experiments showed that the PI3K\(\gamma\) inhibitor did not modulate CXCL10 and RANTES mRNA synthesis by SMC, indicating that this kinase was not directly involved in the proinflammatory responses inherent to SMC. A deleterious role of RANTES in the modulation of inflammatory processes after arterial injury has already been described (Kovacic et al., 2010), whereas the role of CXCL10 is not well defined. CXCL10, also known as IFN-\(\gamma\)-induced protein (IP-10), is involved in CXCR3-positive leukocyte recruitment in atheromas (Mach et al., 1999; Panzer et al., 2006; Proost et al., 2006; Vargas-Inchaustegui et al., 2010). Likewise, blockade or deletion of CXCR3 severely attenuates the recruitment of T cells to the site of inflammation at the arterial wall during the early stages of atherogenesis (Xie et al., 2003; Okamoto et al., 2008). Interestingly, an increase in CXCL10 secretion has been observed in patients with coronary artery disease who had undergone percutaneous transluminal coronary angioplasty and developed restenosis (Kawamura et al., 2003). Finally, interference with CXCL10 in a model of atherosclerosis injury led to a lower intima/media ratio than in a control group, strongly supporting a role for CXCL10 in IH (Zuojun et al., 2012). Nevertheless, the exact function of CXCL10 in arterial injuries is not fully understood. Our observation provides a strong argument in favor of a role for CXCL10 in IH and identifies a novel function for PI3K\(\gamma\) in these processes. In this study, we cannot exclude the possibility of an additional source of IFN-\(\gamma\) other than T cells during IH development. Indeed, Tenger et al. (2005) demonstrated that IFN-\(\gamma\) can be produced by macrophages, NK cells, and vascular cells under the stimulation of IL-18 in the absence of T cells during atherogenesis. A recent paper indicated that the plasma levels of IL-18 correlated with the incidence of in-stent restenosis after percutaneous coronary intervention (Liu et al., 2013), but the exact function of IL-18 in IH development after vascular injury has not yet been evaluated. Further investigation needs to be done to identify the possible role of PI3K\(\gamma\) in IL-18 secretion and its role in IH progression.

To firmly establish PI3K\(\gamma\) as a real therapeutic target, we used pharmacological studies to demonstrate that treatment with a PI3K\(\gamma\) inhibitor, used at a low dose and for a short period, was sufficient to prevent IH induced by vascular trauma. These data were obtained in injured vessels in mice and confirmed in a rat carotid artery balloon injury model that has the advantages of being highly reproducible and of mimicking the overstretch vascular damage induced by angioplasty (Tulis, 2007). Thus, these data validate PI3K\(\gamma\) inhibition as an effective treatment in interventional cardiology. DESs are currently coated with antiproliferative agents such as sirolimus (rapamycin) and paclitaxel. Sirolimus, an inhibitor of the mammalian target of rapamycin (mTOR), is an immunosuppressive agent with antiproliferative, antimigratory, and antiinflammatory properties, exerting its effect by modulating the expression of a large number of intracellular genes (Marx et al., 1995; Poon et al., 2002; Marx et al., 2011). Paclitaxel is a lipophilic molecule derived from the Pacific yew tree Taxus brevifolia and belongs to the family of microtubule-interfering agents. It is capable of inhibiting cellular division and motility by affecting microtubule organization (Belotti et al., 1996; Giannakakou et al., 2001). The clinical introduction of DES has clearly demonstrated a positive effect on IH, but emerging medium- to long-term follow-up data have raised concerns about their safety (Daemen et al., 2007). These molecules both seem to exert their antiproliferative effects not only on SMC but also on endothelial cells, leading to increased rates of late-stent thrombosis in patients with DES (Parry et al., 2005; Daemen et al., 2007). Experimental studies have also demonstrated that reendothelialization is clearly attenuated in patients treated with DES compared with patients with nude bare metal stents (Lüscher et al., 2007). Moreover, a local delivery of paclitaxel in a perivascular injury model applied to mice prone to atherosclerosis has been associated with excessive apoptosis of vascular cells, accompanied by degradation of the internal elastic lamina (Pires et al., 2007). The identification and development of promising novel therapies is therefore of great medical interest. PI3K\(\gamma\) is not ubiquitously expressed and presents an original pattern of expression, with a high level of expression in immune cells and a low level of expression in the cardiovascular system (Fougerat et al., 2009). Thus, its major functions in vivo are in immune modulation and PI3K\(\gamma\) inhibitors are therefore immune modulators rather than having the immunosuppressive effects of drugs such as sirolimus. Our results indicate that PI3K\(\gamma\) inhibition did not interfere with cell proliferation but instead was restricted to the modulation of immune responses, leading to decreased IH without interfering with arterial healing.

Altogether, our data indicate that PI3K\(\gamma\) plays a major role in the initiation and progression of IH by participating in monocyte and T cell recruitment but also by specifically modulating Th1 cytokines that, in combination with Th17 cytokines, are responsible for SMC inflammatory phenotype and especially involved in CXCL10 and RANTES secretion, resulting in the disease progression. These results, added to the benefit of a pharmacological inhibitor of PI3K\(\gamma\) in two rodent models, definitively place PI3K\(\gamma\) as a potential candidate for the prevention of arterial damage in interventional cardiology.

MATERIALS AND METHODS

Animals. PI3K\(\gamma\)-deficient (PI3K\(\gamma\) KO) mice and mice expressing a catalytically inactive form of PI3K\(\gamma\), PI3K\(\gamma\) kinase-dead mice (PI3K\(\gamma\) KD), were from a C57BL/6J background and have been described earlier (Hirsch et al., 2000; Patrucco et al., 2004; Fougerat et al., 2008). Rag2 KO mice on a C57BL/6J background were from the breeding facility of PeCRREF (UMS 06, Anexplor platform). WT, PI3K\(\gamma\) KD, PI3K\(\gamma\) KO, and Rag2 KO mice were maintained at the animal facility of Rangueil (UMS 06, Anexplor platform) and kept under SPF conditions. Sprague Dawley male rats weighing 400–450 g (Janvier SAS) were kept under SPF conditions at the animal facility UTE IRS-UN (Nantes, France). All animal procedures were conducted in accordance with institutional guidelines on Animal Experimentation and were under a French Ministry of Agriculture license.

Femoral artery wire injury in mice. WT, PI3K\(\gamma\) KD, PI3K\(\gamma\) KO, and Rag2 KO male mice aged 8–10 wk were investigated using an established model of femoral artery wire injury (Roque et al., 2000) for IH studies.
In brief, general anesthesia was achieved with 2% isoflurane. Then, the femoral artery was isolated and an incision was made under a surgical microscope (Carl Zeiss). A 0.35-mm diameter angioplasty guide wire with a 0.25-mm tip (gift from Abbott Vascular, Rungis, France) was advanced three times into the artery up to the level of the aortic bifurcation then pulled back. After removal of the wire, the arteriotomy site was ligated. Mice were sacrificed 6 h after the injury for RNA extraction and gene expression analysis, 15 d for ex vivo culture and cytokine production analysis, and 3, 8, or 28 after the injury for histological and immunohistochemical analysis.

Tissue processing and morphometry. IH quantification was performed by the paraffin-embedment technique. At the point of euthanasia, mice were perfused with PBS, followed by 4% paraformaldehyde. Vessels were harvested and fixed in 4% formalin, pH = 8, for 24 h. They were put into paraffin and prepared as slides (4-µm-thick sections). To quantify the rate of IH, sections were stained fused with PBS, followed by 4% paraformaldehyde. Vessels were harvested and the paraffin-embedment technique. At the point of euthanasia, mice were per-

SMC culture and IFN-γ treatment. Rat aortic SMCs were incubated with indicated concentrations of IFN-γ during 48 h, and then washed with PBS and collected in TRIzol reagent (Life Technologies) to quantify CXCL10 and RANTES mRNA expression. RNA extraction, reverse transcription, and qPCR were performed using Prism 5 (GraphPad Software). The expression of CXCL10 and RANTES (forward primer: 5′-GGTCCTCCAGGTTGAGCATGTTGC-3′; reverse primer: 5′-TCCGGATCCAGACAACCCTCTTCTCTC-3′) and RANTES (forward primer: 5′-AACGTGCTCAACCTTTGCAGTCGTC-3′; reverse primer: 5′-CTCTTCTCTGGGTGGGACACAC-3′) expression were analyzed as described above for mouse femoral arteries. The rat Rp113 gene was used as a reference. The results were expressed as fold increase of control condition in absence of PBS or IFN-γ.

Treatment with PI3K抑制剂. A pharmacological inhibitor of PI3K, AS-605240 (Cayman Chemical), was intraperitoneally administered (10 mg/kg/d) to WT mice, PI3K KD mice, or Sprague-Dawley rats. All animals were treated with the PI3K inhibitor from 2 d before until 10 d after femoral artery mechanical injury for mice and carotid artery balloon injury for rats.

Rat carotid artery balloon injury. A total of 16 male 10–mo-old Sprague-Dawley rats weighing 400 to 450 g (Janvier SAS) were used in this study. The balloon denudation injuries were performed in carotid arteries after the procedure previously described (Tulis, 2007). In brief, rats were anesthetized with 2% isoflurane. A midline incision was made in the neck to expose the left external carotid artery. A 2 F Fogarty balloon catheter (Edwards Lifesciences) was introduced into the left external carotid artery and advanced through the common carotid artery to the aortic arch. The balloon was inflated at 3 atm with a medical inflation device (Medtronic), resulting in a 5-mm-long injury. This procedure was repeated two more times (a total of three passes), and then the catheter was removed. The external carotid was ligated, and the incision was sutured. 14 d later, arteries were harvested, flushed with PBS, and fixed with 4% formalin. They were put into paraffin and prepared as slides (4-µm-thick sections). The sections were stained with Masson Trichrome and the quantification was made at 4 sections for each artery (1, 2, 3, and 4 mm from the proximal injury site) using LAS software. Intimal and medial areas were measured and calculated in the same manner as in the mouse injury model.

Statistical analysis. All results are presented as means ± SEM. Comparisons between groups were made using the Mann-Whitney test for independent samples. Outcomes of P < 0.05 were considered to be significant. Analyses were performed using Prism 5 (GraphPad Software).
