Abbreviations used: 7-AAD, 7-amino-actinomycin D; anti–hHB-EFG, anti–human heparin-binding EGF-like growth factor; CCL12, chemokine (C–C motif) ligand 12; CCR, C–C chemokine receptor type; CFDA-SE, carboxyfluorescein diacetate succinimidyl ester; CFU-Ob, colony forming unit-osteoblast; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; DLL, Delta-like ligand; DTR, diphtheria toxin; DTR, diphtheria toxin receptor; G-CSF, granulocyte colony-stimulating factor; GMP, granulocyte and macrophage progenitor; GSEA, gene set enrichment analysis; GvHD, graft-versus-host disease; hHB-EFG, heparin-binding EGF-like growth factor; hHB-EFG, heparin-binding EGF-like growth factor; IC, intracellular; ICAM, intercellular adhesion molecule; ICS, intracellular domain; ICOS, inducible T-cell costimulator; IFN-γ, interferon-γ; IRE, inducible regulatory element; ITAM, immunoreceptor tyrosine-based activation motif; ITAM, immunoreceptor tyrosine-based activation motif; LKS, lineageLoc-kit+Sca+CD48-; LKS, lineageLoc-kit+Sca+CD48-; LPS, lipopolysaccharide; LPS, lipopolysaccharide; M1, pro-inflammatory; M2, anti-inflammatory; MEP, megakaryocyte–erythroid–megakaryocyte–erythroid progenitor; Mib1, Mindbomb1; MPP, multipotent progenitor; Mx1-Cre, B6.Cg-Tg(Mx1-Cre)1Cgn/J; NICD, notch intracellular domain; N.Oc/B.Pm, number of osteoclasts/bone perimeter; Ocn, osteocalcin; OcnCre-Topaz, C57BL/6-Tg(BGLAP-OcnCre-Topaz)1Rowe/J Osterix; P1NP, N-terminal propeptide of type I procollagen; poly(I:C), polyinosinic:polycytidylic acid; Pofu1, protein O-fucosyltransferase 1; PSGL1, P-selectin glycoprotein ligand-1; PTH, parathyroid hormone; SJL, B6; SJL-J–Piper/Pep/J Box/J; ST HSC, short-term hematopoietic stem cell; TRAP, tartrate-resistant acid phosphatase.

Bone mesenchymal cells are central participants in hematopoiesis, providing niches regulating stem and progenitor cells. Lymphopoiesis depends on tissues outside the bone marrow for terminal maturation, but antigen-independent specification of lymphoid lineages is hypothesized to occur in bone marrow. B cell generation has been definitively shown to involve osteolineage cells, whereas T cell generation remains controversial (Visnjic et al., 2004; Zhu et al., 2007; Wu et al., 2008). Deletion of CXCL12 in early osteolineage cells decreased B cell progenitors, whereas deletion of osteocytes produced dramatic metabolic changes, primary damage to thymus, and decreased B and T cell generation through an undefined molecular mechanism (Ding and Morrison, 2013; Greenbaum et al., 2013; Sato et al., 2013). Co-culture of hematopoietic progenitors with bone marrow stroma cells overexpressing Notch ligands enabled T cell lineage generation in vitro (Holmes and Zúñiga-Pflücker, 2009), but whether this recapitulates in vivo events in the bone marrow microenvironment is unclear (Uhmann et al., 2011).

The details of the prethymic process are of increasing interest given that early thymic progenitors may serve as a limiting substrate in immune reconstitution after transplant (Zlotoff et al., 2011). It has been shown that providing...
ex vivo generated human pro–T cells improved T cell reconstitution, thymic architecture, and immunological competence in immunodeficient mice (Zakrzewski et al., 2006; Awong et al., 2013). Therefore, understanding and modulating the production of bone marrow–derived cells that can populate the thymus may have practical consequences in medicine.

RESULTS

We generated mouse strains in which Cre recombinase produced by either the Osteocalcin promoter expressed in mature osteoblasts and osteocytes, or the Osterix promoter expressed in distinct, more immature subsets of bone cells, drives expression of the diphtheria toxin (DT) receptor (DTR) on cell surface (OcnCre+/−;iDTR and OxsCre+/−;iDTR, respectively; OcnCre+/− and OxsCre+/− served as controls). Specific in vivo cell ablation was achieved by intraperitoneal injection of DT. Daily injections into both control and mutant animals began at age 4 wk, and by 6 wk a difference in body size was noted in both the OxsCre+/−;iDTR and OcnCre+/−;iDTR mutant mice compared with littermate controls, which is consistent with inhibition of bone formation (Fig. 1 A). In early experiments, OxsCre+/−;iDTR and OcnCre+/−;iDTR animals without DT treatment were assessed and no phenotypic difference with the OxsCre+/− and OcnCre+/− controls were noted and therefore are not presented further. The T lymphopoenic effect was observed only in the OcnCre+/−;iDTR strain and not the OxsCre+/−;iDTR strain, and thus it is the focus of this work.

Histomorphometry revealed ~70% deletion of osteoblasts and osteocytes in the OcnCre+/−;iDTR mutants (Fig. 1, B and C). To evaluate whether DTR was expressed in the correct cells in bone marrow, immunohistochemistry for DTR without toxin injection was performed and demonstrated overlap with anti–Ocn staining (Fig. 1 D). TUNEL staining after DT administration demonstrated overlap with osteocalcin–specific antibodies (Fig. 1 E), indicating selective cell killing.

Osteoclasts were assessed by TRAP staining and histomorphometry (Fig. 1 F), and measuring endogenous osteoclast activity (Fig. 1 G); these indices were not affected by 2 wk of toxin administration in OcnCre+/−;iDTR mice. Testing whether osteolineage cell depletion might lead to an excess of primitive responding bone progenitor cells, primitive mesenchymal progenitors were assessed by colony forming unit-osteoblast (CFU–Ob) assays and found to be unchanged (Fig. 1 H). No detectable changes in CD31−CD45−Ter119−LepR+ stromal cells were observed (Fig. 1 I).

Despite the changes in bone morphology, overall bone marrow cellularity was unaffected as were blood and bone marrow counts of mature hematopoietic cells except lymphoid cells (Fig. 2 A). This was associated with reduced common lymphoid progenitors (CLPs) within the bone marrow and blood and in particular, CLP with T cell potential (Lineage−Sca+cKit−IL7R−Thy1.2−Ly6D−; Inlay et al., 2009; Manson et al., 2010; Fig. 2, B and C), whereas B-lineage biased CLP (Line age−Sca−cKit−IL7R+Thy1.2−Ly6D+;Tsapogas et al., 2011; Welinder et al., 2011) and progenitors of other lineages, including common myeloid progenitor (CMP), granulocyte and macrophage progenitor (GMP), and megakaryocyte erythroid progenitor (MEP), were not changed (Fig. 2 B). We observed a decrease in bone marrow pro–B subsets, but not in prepro–B cells or downstream pre–B and mature B cells (Fig. 2 D). Spleen weight, cellularity, and B cell count were also not significantly affected. The decrease in B cell intermediates, whereas Ly6D+CLP were normal suggests that specification of B-lineage was not perturbed, but that support of downstream differentiation events was abnormal, as has been seen in other osteolineage modifications (Zhu et al., 2007; Wu et al., 2008; Ding and Morrison, 2013; Greenbaum et al., 2013).

Accompanying the decreased T-competent CLPs in the bone marrow, downstream T-progenitor and mature cells in the thymus were also reduced (Fig. 2 E). We confirmed that Ly6D−CLP are T cell competent by transplantation (Fig. 3 A), and we examined populations others have used in defining T-competent CLP (Flt3+Ly6D−CLP [Karsunky et al., 2008; Inlay et al., 2009] and CLP–1 [Scimone et al., 2006; Krueger and von Bohemmer, 2007]). Decreases in each of these were seen with Ocn− cell depletion and levels were comparable to Ly6D−CLP (unpublished data). Of note, there was no detectable DTR expressed on CLPs to suggest ectopic cell killing by DT.

Despite the increased immunophenotypic hematopoietic stem and progenitor cell (HSPC;Lin−Sca−cKit−CD48−CD150+) number, cell cycling (Fig. 3, B–D), and increased reconstitution at 8 and 12 wk after bone marrow transplantation (Fig. 3 E), no long-term advantage in reconstitution was scored at 16 wk after primary transplantation in a competitive transplant assay. There was also no detectable change in secondary transplantation of cells from the Ocn− deleted animals. These data are consistent with altered cycling of long-term HSC (LT HSC) without an effect on the functionally defined reconstituting ability of these cells by primary and secondary transplantation. The data indicate an effect on short-term HSC (ST HSC) and do not exclude an effect on LT HSC, just not a change in their reconstituting ability from the Ocn+ cell depleted bone marrow. It is possible that longer term exposure to the Ocn+ cell–depleted marrow would affect functional LT HSC number. It is also possible that other important functional changes were induced, but not measured in our studies.

To evaluate the microenvironment dependence of T-lymphopoiesis, WT congenic hematopoietic cells were transplanted into OcnCre+/−;iDTR hosts; the abnormal lymphopoietic phenotype was recapitulated (Fig. 4 A). Reciprocally, OcnCre+/−;iDTR mutant donor bone marrow reverted to normal phenotype when transplanted into WT congenic hosts (Fig. 4 B). Testing whether the effect was on the basis of differential cell proliferation or survival, CLP cell cycling by Ki67 and DAPI staining and cell death by Annexin V and 7–aminactinomycin D (7–AAD) staining were assessed and no significant differences were observed (Fig. 4 C), suggesting alternative mechanisms must be active.
Since Notch is an essential determinant of T-lymphoid commitment and is required for progression through the DN stage (Sambandam et al., 2005; Tan et al., 2005; Visan et al., 2006; Rothenberg et al., 2010; Love and Bhandoola, 2011), we hypothesized that Notch may be participating in the phenotype observed. Notch participation in T-lymphopoiesis before thymic location was previously discounted (Krueger and von Boehmer, 2007), but the cells that were examined have since been shown to be precursors of extrathymic maturation and do not represent thymic progenitors (Luche et al., 2013). In contrast, some studies have reported Notch signaling in bone marrow T cell progenitors (Harman et al., 2005; Maeda et al., 2007). We assessed bone marrow CLP by flow cytometry for evidence of activated, or cleaved Notch and lower levels were observed in OcnCre+/−;iDTR mutants or WT (Ctrl) mice were assessed histologically. Bottom images are at a higher magnification with arrows pointing to empty lacunae within the cortex and altered endosteal surface; images reflect comparable findings in all animals; n = 8/experiment. (C) Osteoblasts in the OcnCre+/−;iDTR and WT mice were quantitated by histomorphometry; n = 7–8 mice/group. Data show mean ± SEM. (D and E) Ocn and DTR expression was examined in bone sections from untreated OcnCre+/−;iDTR by immunohistochemistry using Ocn- and DTR-specific antibodies (D), or by immunofluorescence using Ocn-specific antibodies and TUNEL staining after DT treatment (E); n = 6 mice/group. (F) Osteoclast numbers were assessed by TRAP staining (n = 6 mice/group) and (G) osteoclast activity by collagen breakdown in sera using ELISA assay; n = 7–8 mice/group. Data show mean ± SEM. (H) Mesenchymal progenitor activity in the bone marrow of OcnCre+/−;iDTR mutants or WT controls was assessed by CFU-Ob assay; n = 9 mice/group. Data show mean ± SEM. (I) CD31−CD45−Ter119−LepR+ cells in the bone marrow stroma of OcnCre+/−;iDTR mutants and controls were quantified by flow cytometry; n = 6–7 mice/group. Data show mean ± SEM. (A–I) For each experiment, 3–6 independent repeats were performed.
Figure 2. Ocn+ cell deletion decreases T cell competent lymphoid progenitors and T lineage cells. (A) Flow cytometric evaluation of lymphoid, myeloid, erythroid, and megakaryocytic mature cells and (B) T cell competent (Ly6D−) CLP, B potential enriched (Ly6D+) CLP, CMP, GMP, and MEP populations in the bone marrow of control and Ocn+ cell–deleted animals. Minimum of three independent experiments; n = 8–16 mice/group. Data show mean ± SEM. (C) Gene set enrichment analysis (GSEA) comparing Ly6D− CLP versus multipotent progenitor (MPP) microarray data. Experiment was performed twice independently; n = 3/experiment. (D) Flow cytometric quantification of different stages of B progenitors and mature cells in the bone marrow of OcnCre;iDTR mutant and control littermates. Experiment was performed twice independently; n = 5–6 mice/group. Data show mean ± SEM. (E) Flow cytometric quantification of T cell subsets in the thymus. Minimum of four independent experiments; n = 8–12 mice/group. Data show mean ± SEM.
We tested whether Notch ligand expression specifically by Ocn+ cells caused the lymphopoietic phenotype using the conditional OcnCre;iDTR strain. Ocn+ cell-specific DLL4 deletion resulted in significantly reduced Notch-activated CLP, T cell–competent Ly6D−CLP, and CCR7-expressing Ly6D−CLP (Fig. 6 A, discussed in the following paragraphs), with a decrease comparable in magnitude to that seen with Ocn+ cell depletion (Fig. 2 B). Thymic intermediates and blood T-lymphocytes were also decreased (Fig. 6 A).

Similar changes were noted when Mib1 (Mindbomb1, Mib1) encoding an E3-ligase necessary for Notch ligand processing (Koo et al., 2005), was deleted in Ocn+ cells (Fig. 6 B). Together, these data demonstrate the role of Notch ligands expressed by Ocn+ cells as the basis for the decrease in T-lymphopoiesis.

Figure 3. Lymphopenic phenotype in OcnCre;iDTR mice was not caused by a stem cell defect. (A) 44,000 flow sorted Ly6D− or Ly6D+ CLPs from SJL (CD45.1) mice were intravenously transplanted into each of 10 nonirradiated C57BL/6J (CD45.2) recipients. Recipients were bled 3 wk after transplant for enumeration of donor-derived B and T reconstitution by staining with CD45.1, B220, CD4 and CD8 antibodies and analysis by flow cytometry. Experiment was performed twice independently; n = 10/experiment. Data show mean ± SEM. (B) Mature osteolineage cells were deleted from OcnCre;iDTR mice and hematopoietic stem cells (LKS SLAM), Lineage−ict-Kit+Sca− (LKS) multipotent progenitors, and Lineage−ict-Kit+Sca− cells were enumerated by flow cytometry. (C) Cell cycle analysis of the indicated cell populations was performed by flow cytometry. (D) Frequency of apoptotic (AnnexinV−7-AAD−) and necrotic (AnnexinV−7-AAD+) LKS SLAM, LKS, and Lineage−ict-Kit+Sca− cells was assessed. Experiments were repeated 3 times independently; n = 5–16 mice/group. Data show mean ± SEM. (E) CD45.2 OcnCre;iDTR mutant or control donor cells were mixed with CD45.1 SJL donor cells in a 1:1 ratio, injected into primary SJL recipients. Reconstitution was assessed at 8, 12, and 16 wk after transplantation. Bone marrow cells from primary recipients were harvested and transplanted into secondary recipients. Reconstitution was assessed at 8, 12, and 16 wk following transplantation. Transplantation was performed twice independently; n = 20–22 mice/experiment. Data show mean ± SEM.
Dll4 specifies thymus-seeding progenitors | Yu et al.

models confirm the role of Notch signaling in early T-lineage differentiation: altering bone marrow generation of thymic progenitors. Further, the comparable changes seen when either control or mutant CD45.2 OcnCre^{+/−};iDTR bone marrow competitors in a 1:1 ratio and transplanted into lethally irradiated WT SJL recipients. Animals were bled at 8, 12, and 16 wk after transplantation for blood count and hematopoietic reconstitution by flow cytometry. (A and B) Two independent transplantations were performed; n = 20–22 mice/experiment. Data show mean ± SEM. (C) Cell cycle status, apoptosis, and necrosis in CLPs in OcnCre^{+/−};iDTR mutants and controls were assessed by flow cytometry. 2 independent experiments; n = 5–6 mice/group. Data show mean ± SEM.

Testing of Notch-signaling in hematopoietic cells was then performed by several models. The Protein O-fucosyltransferase1 gene product (Pofut1) transfers O-fucose to the EGF-like repeats on Notch and is required for the binding of Delta-like ligands (Yao et al., 2011). Deleting it using Mx1-Cre^{+/−};Pofut1^{−/−} mice revealed decreased CLP and Ly6D^{−}−CLP compared with controls (Fig. 7 A). Because Pofut1 does not act exclusively on Notch receptors, the downstream signaling mediator RBP-Jκ was also assessed. Mx1-Cre deletion of RBP-Jκ compromised bone marrow CLP and Ly6D^{−}−CLP (Fig. 7 B). Further, intrafemoral injection of the γ-secretase inhibitor N-[N-(3,5-difluorophenacetyl)-l-alanyl]-S-phenylglycine t-butyl ester (DAPT) reduced CLP and Ly6D^{−}−CLP on the ipsilateral side (Fig. 8 A). Lastly, intravenously transplanted 10^6 Lin^{−} hematopoietic progenitor cells from Mx1Cre;LSL-NICD-GFP mice expressing a dominant-active Notch intracellular domain (NICD) rescued the OcnCre;iDTR lymphoid defect in Ly6D^{−}−CLP and Ly6D^{−}CCR7^{−}−CLP compared with Mx1Cre;LSL-GFP controls (Fig. 8 B). Collectively, these in vivo genetic mouse

Figure 4. Ocn^{+} cell regulation of T lymphopoiesis is dependent on bone marrow microenvironment. (A) 10^6 WT CD45.1 hematopoietic bone marrow cells were transplanted into lethally irradiated CD45.1 OcnCre;iDTR hosts that were untreated or treated with DT. Animals were bled at 8, 12, and 16 wk after transplantation for blood count and assessment of hematopoietic reconstitution by flow cytometry. (B) 5 × 10^5 bone marrow cells from either control or mutant CD45.2 OcnCre^{+/−};iDTR donors were mixed with 5 × 10^5 CD45.1 SJL bone marrow competitors in a 1:1 ratio and transplanted into lethally irradiated WT SJL recipients. Animals were bled at 8, 12, and 16 wk after transplantation for blood count and hematopoietic reconstitution by flow cytometry. (A and B) Two independent transplantations were performed; n = 20–22 mice/experiment. Data show mean ± SEM. (C) Cell cycle status, apoptosis, and necrosis in CLPs in OcnCre^{+/−};iDTR mutants and controls were assessed by flow cytometry. 2 independent experiments; n = 5–6 mice/group. Data show mean ± SEM.
These data argue against an altered thymic microenvironment (or metabolic milieu) induced by the deletion of Ocn+ cells or DT administration as the basis for altered T cell differentiation. They also argue against, but cannot definitively exclude, secondary effects of stress on the lymphopoietic phenotype.

Examining whether the thymocyte production defects were cell autonomous, we adoptively transferred $3 \times 10^4$ Ly6D-CLPs cells from bone marrow of control or Ocn+ cell-depleted animals intrathymically into WT mice. After 3 wk, no evidence for a defect in the thymocyte maturation sequence was observed for cells derived from the context of the Ocn+ cell–depleted bone marrow (Fig. 9 A). The reversal of abnormalities in all T-intermediate stages in the thymus also led to fully restored mature CD4+ and CD8+ populations in the bone marrow (Fig. 9 A). Similar results were observed using Lin- Sca-Kit+Flt3+ cells. No extrathymic development was observed in organs, including bone marrow, spleen, lymph node, and intestine. Therefore, the perturbation of T cell development induced by Ocn+ cell depletion appears to be in enabling bone marrow thymus-seeding cell formation and migration, not in impaired differentiation capacity of cells once they arrive in the thymus.

Figure 5. Reduced DLL4 in the bone marrow of Ocn+ cell-depleted mice led to decreased Notch signaling in CLP.
(A) Intracellular Notch signaling was assessed by flow cytometry in the indicated cell populations. Representative flow plots are shown, and data are summarized by dot plot (right). Three independent experiments; $n = 16–17$ mice/group. Data show mean ± SEM.
(B) Expression of the indicated Notch target genes in Ly6D-CLP from OcnCre+;iDTR mutants and controls. Mutant and WT mice were examined after 28 d after DT treatment. Three independent experiments; $n = 12–14$ mice/group. Data show mean ± SEM. (C) Expression of the Notch ligands in the bones of OcnCre+;iDTR DT-treated and control animals was assessed by qPCR. Two independent experiments; $n = 12$ mice/group. Data show mean ± SEM. (D) DLL4 expression in bone sections from control or Ocn+ cell-deleted animals was assessed by immunohistochemistry. Two independent experiments; $n = 6$ mice/group. Data show mean ± SEM. (E) Gene set enrichment analysis (GSEA) comparing Ly6D-CLP versus MPP microarray data. Experiment performed twice; $n = 3$/experiment. Data show mean ± SEM. (F) Gene set enrichment analysis (GSEA) comparing Ly6D-CLP microarray data obtained from OcnCre;iDTR control versus mutant mice. Experiment was performed twice independently; $n = 3–4$/experiment.

Figure 6. Conditional deletion of DLL4 or Notch ligands in Ocn+ cells impaired T lymphopoiesis. (A) OcnCreER+/-;Dll4fl/fl mutants and OcnCreER+/-;Dll4+/+ control littermates were injected with 2mg 4-OH-tamoxifen/15 g BW eight times over 4 wk to induce deletion of the DLL4 ligand. Mice were harvested immediately after 4 wk of deletion and bone marrow CLPs, thymic T cell progenitors, and peripheral blood mature T cells were enumerated by flow cytometry. Experiment was performed 3 times independently; n = 9–10 mice/group. Data show mean ± SEM. (B) OcnCreER+/-;Mib1fl/fl mutants and OcnCreER+/-;Mib1+/+ control littermates were injected with 2 mg 4-OH-tamoxifen/15 g BW 8 times over 4 wk to induce deletion of the Mib1 gene. Mice were harvested immediately after 4 wk of deletion and bone marrow CLPs, thymic T cell progenitors, and peripheral blood mature T cells were enumerated by flow cytometry. Experiment was performed twice independently; n = 6–8 mice/group. Data show mean ± SEM.

Because Notch has been reported to mediate the expression of chemokine receptors in T cell leukemia (Mirandola et al., 2012), we assessed whether OcnCre+/-;idTR bone marrow cells properly express the chemokine receptors (Krueger et al., 2010) or ligands (Sultana et al., 2012) necessary for thymic seeding. We observed modestly decreased CCR7 expression intensity in the CLPs without changes in CCR9 or PSGL1, but with a significant decrease in the number of CCR7+CLP and PSGL1+CLP (Fig. 9 B). CCR7+CLP was also decreased in OcnCreER+/-;Dll4−/−, OcnCreER+/-;Mib1−/−, Mx1Cre+/-;Pofut1−/−, Mx1Cre+/-;RBPjk−/− mice, and γ-secretase injected femurs compared with littermate controls (Figs. 6–8). Together, these data indicate that Ocn+ cell depletion results in decreased thymic-seeding progenitors and in decreased production of the thymic homing molecule, CCR7, in those progenitors.
To test whether thymus migratory capacity of bone marrow cells was reduced in vivo, we conducted competitive homing experiments. LKS Flt3+ cells (1.5 × 10^6) or CLPs (two doses: 3.5 × 10^5 or 10^6) from control or Ocn−/− cell-depleted mice were isolated, stained with distinctive fluorescent tags, and intravenously injected at a 1:1 ratio into SJL recipients (Fig. 9 C). In parallel, equivalent cells sorted from age matched CCR7−/− mice labeled with a distinctive fluorescent tag were used as positive controls for homing defective cells and similarly competed in a 1:1 ratio into recipients. Recipient thymi were evaluated 24 h after transplant. OcnCre−/−;iDTR mutant or CCR7−/− donor cells were similarly compromised in thymic homing ability compared with controls (Fig. 9 C). These data suggest that the reduction in thymocytes may be due to failure to generate thymic-homing competent cells in the bone marrow of Ocn−/− cell
deleted animals. The defect in homing capacity may be caused by decreased CCR7 or PSGL1 or the combination of the two in the absence of Ocn+ cells in the bone marrow.

To test our hypothesis that Ocn+ cells instruct early T-lineage specification in bone marrow through DLL4, we injected the Ocn+ cell–depleted animals with recombinant mouse DLL4. Although this ligand is generally cell associated, it has been shown by others to induce Notch activation when administered as a recombinant protein (Androussis-Theotokis et al., 2006; Benedito et al., 2012; Moya et al., 2012). Control and mutant OcnCre+/-;iDTR mice were treated with daily DT injections from day -19. At day -5, mutant OcnCre+/-;iDTR mice were co-injected with either 100 ng/g BW or 1 µg/g BW of DLL4 intravenously. All mice were harvested at day 0. Results showed that injection of a high concentration of DLL4 into the bloodstream rescued the OcnCre+/-;iDTR bone marrow CLP and increased CCR7 expression on CLPs (Fig. 10 A)
Figure 9. Ocns cell–depleted animals had intact thymic function but impaired CLP homing ability. (A) 30,000 flow sorted bone marrow CLPs from diphtheria treated OcnsCre−/−;iDTR animals (Mut) or controls (Ctrl) were injected into the thymus of either OcnsCre−/−;iDTR DT treated (Mut) or control (Ctrl) animals. Injection of PBS served as mock controls. Thymic T progenitor and mature populations were assessed after 4 wk. Two independent experiments; n = 4–6 mice/group. Data show mean ± SEM. (B) CCR7, CCR9, and PSGL1 cell surface expression on CLP from Ocns+ cell–depleted or control mice was assessed by flow cytometry. Panels on the left show expression levels (indicated by fluorescent intensity on the y axis) and dot plots on the right show numbers of cells with positive expression. Minimum two independent experiments; n = 8–10 mice/group. Data show mean ± SEM. (C) CLPs from diphtheria-treated OcnsCre;iDTR control and mutant mice were labeled with green and red fluorescent dyes, respectively, mixed in a 1:1 ratio and transplanted intravenously into congenic SJL recipients, and harvested 24 h after transplant. Equal number of CLPs harvested from CCR7−/− mice was used as another control and competed with OcnsCre;iDTR mutant CLPs in a similar manner. Donor-derived cells were enumerated from recipient thymi 24 h after transplant. Experiment was repeated with reciprocal dye to control for dye labeling efficiency. 2 independent experiments; n = 10 mice/experiment. Data show mean ± SEM.

and subsequent thymic T cell development (Fig. 10, B–K), resulting in normalized mature T number in the bone marrow (Fig. 10 L). Supplement of a low concentration of DLL4 only partially increased bone marrow CLP (Fig. 10 A), but restored all subsequent stages of T development downstream in the thymus (Fig. 10, B–K). These data are consistent with
DLL4 acting at the level of both the bone marrow and thymus. The impact of DLL4 was both in cell number and CCR7 expression in the bone marrow consistent with a role in both processes.

**DISCUSSION**

Immune reconstitution after allogeneic hematopoietic stem cell transplantation is a major clinical problem resulting in significant patient morbidity and mortality. We tested whether the number of Ocn+ cells might be compromised in vivo under settings related to hematopoietic stem cell transplantation. We generated mice that simultaneously label Osx-expressing cells and Ocn-expressing cells with distinct fluorescence markers and enumerated the cells by flow cytometry. A specific and marked reduction of Ocn+ cells was observed in a model of allogeneic transplantation and graft-versus-host disease (GVHD). The number of Osx+, Osx+Ocn+, and Ocn+ cells in femurs were enumerated by FACS. Experiment was performed twice; n = 8 mice/experiment. Results are means ± SEM.

Figure 10. In vivo rescue of T lineage defect by intravenous infusion of DLL4. (A–L) OcnCre;iDTR control and mutant mice were first treated with DT for 21 d to induce Ocn+ cell deletion, then injected with recombinant DLL4 intravenously at two different dosages: 100 ng/g BW or 1 µg/g BW. Flow cytometric evaluation of effects on the number of bone marrow CLPs (A), thymic T cell intermediates (B–K), and mature T cells circulated back to the bone marrow (L). Experiments was performed twice independently; n = 6–12 mice/group. Data show mean ± SEM. (M) Transgenic mice with osteolineage cells at the progenitor stage (Osx+) labeled red, intermediate stage (Osx+Ocn+) labeled yellow, and mature stage (Ocn+) labeled green were treated with either saline control (CNTR), parathyroid hormone (PTH), granulocyte colony-stimulating factor (G-CSF), IFN-γ, LPS, or transplanted in a noncompatible setting to elicit graft-versus-host disease (GVHD). The number of Osx+, Osx+Ocn+, and Ocn+ cells in femurs were enumerated by FACS. Experiment was performed twice; n = 8 mice/experiment. Results are means ± SEM.

a particularly immunosuppressive clinical scenario and one where T cell reconstitution is markedly delayed. We also noted that granulocyte colony-stimulating factor (G-CSF), commonly used after transplantation, adversely affected Ocn+ cells as did γ-interferon, a cytokine associated with immune activation with infection or GVHD (Fig. 10 M). These data suggest that the context of allogeneic hematopoietic stem cell transplantation may adversely affect critical components of the niche for full immunological reconstitution.

These studies indicate that Ocn+ bone cells may enable T-lineage competent cell production and thymus seeding through expression of DLL4. Although DLL4 is well defined as necessary to enforce T-lineage differentiation in the thymus and cells of multipotency are present in the thymus (Hozumi et al., 2008; Koch et al., 2008; Mohtashani et al., 2010), the data here suggest a contribution of bone cells and bone marrow to
robust T-lymphopoesis in young adult animals. Other studies of modifying bone cell CCL12 production or deletion of DMP-1+ cells have indicated, respectively defects in CLP (but not mature T cells) or of thymus, T cells, and B cells and metabolism broadly (Ding and Morrison, 2013; Greenbaum et al., 2013; Sato et al., 2013). The lack of T cell phenotype in our OsnCre+/−;iDTR model was unexpected and there could be several explanations. Differences in Cre deletion efficiency could be one reason, as we achieved ~50% cell deletion in the OsnCre+/−;iDTR model compared with 70% deletion in the OcnCre+/−;iDTR system. Second, the relative balance of Osn+ cells versus Ocn+ cells in the bone marrow may be important for creating a B versus T-progenitor niche. Systemic or indirect effects imposed by Osn+ or Ocn+ cell deletion also remains possible. Based on our current data, we present a model where a specific Notch-ligand, produced by a specific subset of bone cells drive T-lineage competence and enable thymus-seeding cell production. This model may inform strategies to improve T-lineage production and reconstitution in settings of disease, particularly because the bone cells involved appear to be susceptible to loss in contexts like transplantation where T cell generation is of great clinical consequence.

MATERIALS AND METHODS

Mouse models. All single transgenic mouse strains were maintained in a C57BL/6J background by backcrossing to C57BL/6J for at least 10 backcrosses. To specifically delete mature osteolineage cells, the OC−/cre strain (from T.L. Clemens, Johns Hopkins University, MD; Zhang et al., 2002), which expressed Cre under the osteocalcin promoter was crossed to the iDTR strain (Buch et al., 2005). Temporally controlled cell ablation was achieved upon injection of DT into the OcnCre−/−;iDTR strain. Similarly, Ocn+ cell deletion was achieved by crossing the Osn1-GFP::Cre mouse (Rodda and McMahon, 2006) to the iDTR strain. To study the effect of Ocn+ cells on hematopoiesis, OcnCre−/− injected with DT or OcnCre+/−;iDTR injected with PBS served as controls while OcnCre+/−;iDTR injected with DT were used as mutants. For osteoprogenitor deletion, control mice were OssCre−/− injected with DT or OssCre+/−;iDTR injected with PBS, whereas OssCre+/−;iDTR injected with DT served as mutants. For most experiments, 25 ng DT in PBS/g of body weight was injected daily into both control and mutant animals for 28 d from 4 wk of age to achieve an acute deletion of specific osteolineage populations. Mice were harvested for analysis the next day after the last dose of diphtheria injection.

Immunohistochemistry. Expression of the DT receptor on cell surface was detected by immunohistochemical staining of paraffin sections with anti-human heparin-binding EGF-like growth factor (anti–hHB-EGF) antibody (R&D Systems; AF-259-NA). In brief, deparaffinized and rehydrated sections were treated with 0.1% trypsin for antigen unmasking and 3% H2O2 to block endogenous peroxidase activity. Sections were then blocked with reagent containing 5% animal serum in PBS-T for 1 h. Goat polyclonal anti–hHB-EGF antibody was used at 1:25 dilution, coupled with horse biotinylated anti–goat IgG secondary antibody (Vector Lab) at 1:400 dilution. Rabbit polyclonal anti-Dll4 antibody (Abcam; ab84081) was used at 1:50 dilution, coupled with biotinylated anti–rabbit antibody at 1:250 dilution (Vector Lab). After antibody staining, sections were washed in PBS-T, treated with VECTASTAIN ABC kit for biotin-streptavidin signal amplification, and subsequently visualized by DAB Peroxidase Substrate kit. Phycocerythrin-conjugated anti–PECAM1 antibody (BD) was applied at 1:100 dilution and mounted with DAPI containing mounting medium. Ocn expressing mature osteoblasts and osteocytes were recognized by goat polyclonal anti-osteocalcin antibody (Santa Cruz Biotechnology, Inc.; sc-18322) at 1:100 dilution followed by donkey anti–goat IgG secondary antibody conjugated to Alexa Fluor 488 at 1:4,000 dilution. Green fluorescent osteocalcin-antibody stainings were individually superimposed with red fluorescent TUNEL (In situ Cell Death Detection kit TMR Red, Roche) staining.

Colony forming unit–osteoblast (CFU-Ob) assay. Bone marrow cells were collected from each mouse by flushing end-excised femurs and tibiae with PBS containing penicillin and streptomycin. Collected bone marrow cells were incubated with ACK lysis buffer to remove red blood cells, washed with PBS, and plated at 105 cells per well in a 6-well plate supplemented with DMEM and 10% FBS. Nonadherent cells were removed on the fifth day and adherent cells were replated at 5 × 104 cells per well and cultured in the same media until confluent. Once cultures reached confluency, medium was changed into DMEM containing 50 µg/ml acetic acid, 10−9 M dexamethasone, and 8 mM β-glycerophosphate and changed every 2–3 d to induce osteogenic differentiation. 14 d later, cultures were fixed in 4% PFA, stained with hematoxylin and eosin for general morphology, as well as von Kossa and Goldner trichrome. Tartrate-resistant acid phosphatase (TRAP) staining was used to reveal osteoclasts. Alteration of osteoblastic activity was assessed by measuring serum levels of osteocalcin and N-terminal propeptide of type I procollagen (P1NP) using RatLaps ELISA kits (n = 22–24). Changes in osteocastic bone resorption was assessed by measuring the C-terminal telopeptides of collagen type I fragments in mouse serum using RatLaps EIA kit (n = 22–24).

Bone histology. Tibiae were fixed in 70% ethanol and embedded without demineralization in methyl methacyrate for histomorphometric analysis. 5-µm sections were stained with toluidine blue to quantify static parameters, including bone volume per tissue volume, trabecular number, trabecular separation, osteoblast and osteocyte number per tissue area, and osteoclast number per bone perimeter. Unstained sections were used to measure dynamic parameters, including bone formation rate per tissue volume. A sampling site with an area of ~1.4 mm2 was established in the secondary spongiosa of the metaphysis at 450 µm below the growth plate. A standard histomorphometric analysis was performed using the OsteoMeasure system (Osteometrics, Inc.) and the results were expressed according to standardized nomenclature (Parfitt et al., 1987). Statistical analysis was achieved using the nonparametric Mann–Whitney test (p = 7–8). For paraffin sections, femurs and tibiae were collected and fixed in 4% paraformaldehyde overnight, decalcified with 20% EDTA for 1 wk, washed in PBS, dehydrated through a series of alcohol changes up to 70% EtOH, and embedded in paraffin. Paraffin sections were stained with hematoxylin and eosin for general morphology, as well as von Kossa and Goldner trichrome. Tartrate-resistant acid phosphatase (TRAP) staining was used to reveal osteoclasts. Alteration of osteoblastic activity was assessed by measuring serum levels of osteocalcin and N-terminal propeptide of type I procollagen (P1NP) using RatLaps ELISA kits (n = 22–24). Changes in osteocastic bone resorption was assessed by measuring the C-terminal telopeptides of collagen type I fragments in mouse serum using RatLaps EIA kit (n = 22–24).
Flow cytometry. Before sacrifice, peripheral blood was collected from each mouse and subjected to complete blood cell count. For each mouse, mature, emperipolesis, CD45.2-APC (Gr1-FITC), E41-FITC, B220-APC, and B220-PE antibodies to measure lineage reconstitution by flow cytometry. At 16 wk after transplantation, all recipients were sacrificed. Red blood cells were lysed and total bone marrow cells were stained with CD45.1-PE, CD45.2-APC, to measure donor reconstitution by individual lineages using flow cytometry.

Transplantation. For transplantation of WT hematopoietic cells into Ocn+ cell depleted mutant environment, 1 × 10^6 bone marrow mononuclear cells from 6-wk-old SJL donors were transplanted into each of 10 age-matched congenic SJL recipients. For both control and donor group, a total of 10^6 mice were competed with 5 × 10^5 bone marrow mononuclear cells from 6-wk-old mutant OcnCre+/-;iDTR animals into WT recipients, 5 × 10^6 bone marrow mononuclear cells from 6-wk-old mutant OcnCre+/-;iDTR mutant recipient (CD45.1-PE) by retro-orbital injection. The same number of progenitor cells were stained for CD45.1-PE, CD45.2-APC to measure donor reconstitution by flow cytometry. At 16 wk after transplantation, all recipients were sacrificed. Bone marrow cells were harvested from femurs, tibiae, iliac crests, and red blood cell depleted mutant environment, 1 × 10^6 bone marrow mononuclear cells from 6-wk-old SJL donors were transplanted into each of 10 age-matched congenic SJL mice using FACSAria (BD). Ly6D (Lin+; Sca+cKit+IL7RThy1.2Ly6D+) or Flt3+ LKS (Lin−; Sca+cKit+Flt3+) cells (30,000 or 10,000 Ly6D− CLPs (Lin−; Sca+cKit+IL7RThy1.2Ly6D−) were sorted from OcnCre+/-;DTR control and mutant donors (CD45.2-Pacific Blue), labeled with 10 μM CFDA-SE (Invitrogen) and 1 μg/ml VivoTag680 (VT680, VisEn Medical), respectively, mixed in a 1:1 ratio, and transplanted into each congenic SJL recipient (CD45.1-PE) by retro-orbital injection. The same number of progenitor cells sorted from CCR7+/− mice were used as control to compete with OcnCre+/-;DTR mutant donors. Recipient thymi were harvested 24 h after transplant and donor-derived cells (CD45.2-Pacific Blue) from OcnCre+/-;DTR control (CFDA-SE) and mutant (VT680) were enumerated by flow cytometry. To account for the housekeeping GAPDH gene for normalization.

Quantitative PCR. Flow sorted cells were extracted for RNA using the RNeagous−4PCR kit (Ambion). Fluorescently labeled bone marrow cells from 6-wk-old SJL donors were transplanted into each of 10 age-matched congenic SJL recipients. For both control and donor group, a total of 10^6 mice were competed with 5 × 10^5 bone marrow mononuclear cells from 6-wk-old mutant OcnCre+/-;iDTR mutant recipient (CD45.1-PE) by retro-orbital injection. The same number of progenitor cells sorted from CCR7+/− mice were used as control to compete with OcnCre+/-;DTR mutant donors. Recipient thymi were harvested 24 h after transplant and donor-derived cells (CD45.2-Pacific Blue) from OcnCre+/-;DTR control (CFDA-SE) and mutant (VT680) were enumerated by flow cytometry. To account for the housekeeping GAPDH gene for normalization.

Competitive thymic homing experiment. 35,000 or 10,000 Ly6D− CLPs (Lin−; Sca+cKit+IL7RThy1.2Ly6D−) were sorted from OcnCre+/-;DTR control and mutant donors (CD45.2-Pacific Blue), labeled with 10 μM CFDA-SE (Invitrogen) and 1 μg/ml VivoTag680 (VT680, VisEn Medical), respectively, mixed in a 1:1 ratio, and transplanted into each congenic SJL recipient (CD45.1-PE) by retro-orbital injection. The same number of progenitor cells sorted from CCR7+/− mice were used as control to compete with OcnCre+/-;DTR mutant donors. Recipient thymi were harvested 24 h after transplant and donor-derived cells (CD45.2-Pacific Blue) from OcnCre+/-;DTR control (CFDA-SE) and mutant (VT680) were enumerated by flow cytometry. To account for the housekeeping GAPDH gene for normalization.

Intrathymic adoptive transfer assay. We follow the procedure described previously (Goldschneider et al., 1986) with the following modifications: Mice were anesthetized with intraperitoneal injection of a mixture of ketamine (100 mg/kg) and xylazine (10 mg/kg). Sorted Ly6D− CLPs (Lin−; Sca+cKit+IL7RThy1.2Ly6D−) or Flt3+ LKS (Lin−; Sca+cKit+Flt3+) cells (30,000 cells in 20 μl PBS) were injected at two sites in the anterior superior portion of each thymus lobe (10 μl/site) using a Hamilton syringe mounted with a 30-gauge needle. After surgical procedure, mice were placed under the heat lamp for 30 min to aid recovery from anesthesia and were monitored daily for any signs of discomfort after the Pain Assessment Protocol published by the National Research Council (US) Committee. Mice that demonstrated signs of persistent pain were euthanized. Mice were sacrificed on the 14th day after surgery by CO2 asphyxiation and cervical dislocation, and thymi were harvested for cell analysis by flow cytometry.
DLL4 rescue experiment. Control OcnCre™/− and mutant OcnCre™/−/−dTR mice were intraperitoneally injected with 100 ng/g BW DT daily since day −19. Starting from day −5, OcnCre/DTR mutants were co-injected daily with either 100 ng/g BW or 1 µg/g BW of recombinant mouse DLL4 (B&D Systems) intravenously. All mice were harvested at day 0 for bone marrow cells and thymic collection. Bone marrow cells were red blood cell lysed and stained for CLP, CD4, and CD8-specific antibodies, whereas thymocytes were stained for T developmental specific antibodies for flow cytometric analysis. The experiment was repeated twice.

Intrathelial injection of DAPT. We injected 10 µl of either 2.5 mM DAPT (EMD Millipore) or PBS as control into the left tibia of each of eight C57BL/6 mice at day −12, −9, and −6, and harvested the left femur, thymus, and peripheral blood at day 0 for flow cytometric analysis.

GvHD model. For the induction of GvHD, 5 × 10^6 bone marrow cells were mixed with 2 × 10^6 CD4/CD8+ splenic T cells from C57BL/6 donor mice. The purification of the CD4/8+ T cells was achieved using the MACS LD cell separation columns and the MACS Streptavidin MicroBeads (Miltenyi Biotec). Mice were monitored for signs of GvHD daily and the degree of clinical GvHD was assessed weekly by a scoring system that sums changes in five clinical parameters: weight loss, posture (hunching), activity, fur texture and skin integrity. 2 wk after the transplantation, mice were sacrificed.

Statistical analysis. Statistical analysis of all paired experiments was analyzed by two-tailed Student’s t test. All graphs were represented with mean and standard error of the mean, where *P < 0.05; **P < 0.01; ***P < 0.001; and ****P < 0.0001, unless otherwise stated. Statistical comparison of multiple parameters were analyzed by One-way ANOVA, followed by Bonferroni post-test, where *P < 0.05; **P < 0.01; ***P < 0.001; and ****P < 0.0001.

Online supplemental material. Fig. S1 shows flow gating strategies for bone marrow singlets and B cells. Fig. S2 depicts flow gating strategies for bone marrow T cells, monocytes, granulocytes, erythroid cells, and megakaryocytes. Fig. S3 illustrates flow gating strategies for bone marrow hematopoietic progenitor cells. Fig. S4 diagrams flow gating strategies for intrathyrmic T cells. Fig. S5 describes flow gating strategies for LeP+* cells in the bone marrow stroma. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20141843/DC1.

We are grateful to the following investigators for the original generation and sharing of strains: Dr. Thomas L. Clemens (OC-B6), Dr. Young-Yun Kong (Mib1F/F), Dr. Pamela Stanley (Pofut1F/F), and Dr. Tatsuko Honjo (RBP-Jf/f). The authors would like to thank Oliver Hofmann and John Hutchinson of the HSPH Bioinformatics Core, Harvard School of Public Health, Boston, MA for assistance with microarray analysis.
