Abrogation of CD30 and OX40 signals prevents autoimmune disease in FoxP3-deficient mice

Fabrina M. Gaspal, David Withers, Manoj Saini, Vasileios Bekiaris, Fiona M. McConnell, Andrea White, Mahmood Khan, Hideo Yagita, Lucy S.K. Walker, Graham Anderson, and Peter J.L. Lane

Our previous studies have implicated signaling through the tumor necrosis family receptors OX40 and CD30 as critical for maintaining CD4 memory responses. We show that signals through both molecules are also required for CD4 effector-mediated autoimmune tissue damage. Under normal circumstances, male mice deficient in the forkhead transcription factor FoxP3, which lack regulatory CD4 T cells, develop lethal autoimmune disease in the first few weeks of life. However, in the combined absence of OX40 and CD30, FoxP3-deficient mice develop normally and breed successfully. The extensive tissue infiltration and organ destruction characteristic of FoxP3 disease does not appear in these mice, and their mortality is not associated with autoimmunity. Although the absence of OX40 plays the dominant role, FoxP3-deficient mice sufficient in CD30 but deficient in OX40 signals still eventually develop lethal disease. This result was supported by the observation that blocking antibodies to OX40 and CD30 ligands also abrogated disease mediated by FoxP3-deficient T cells. These observations identify OX40 and CD30 signals as essential for the development of clinically relevant CD4-dependent autoimmunity and suggest that combination therapies that abrogate these signals might be used to treat established human autoimmune diseases.

The Journal of Experimental Medicine
RESULTS AND DISCUSSION

Generation and phenotype of FoxP3<sup>−/−</sup> mice deficient in OX40 and CD30

To investigate the impact of abrogation of OX40 and CD30 signals on the development of autoimmunity in FoxP3<sup>−/−</sup> mice, male C57BL/6 mice, deficient in both OX40 and CD30 (double [d] KO), were crossed with females with a heterozygous null allele for the X-linked gene FoxP3 (FoxP3<sup>het</sup>). As expected, ~50% of male offspring heterozygous for expression of OX40 and CD30 (dKO<sup>het</sup>) were FoxP3 deficient and developed lethal autoimmune disease at ~4 wk (Fig. 1 A), characterized by weight loss (Fig. 1 B) and scurfy phenotype (Fig. 1 C). Because OX40 and CD30 are linked genetically, offspring have a high probability of inheriting deficiency in both genes as a haplotype. Consequently, after an F1 intercross between male dKO mice and FoxP3<sup>het</sup>dKO<sup>het</sup> females, ~50% of the F2 male progeny were FoxP3 deficient. Within this population ~50% were dKO<sup>het</sup> and ~50% dKO. In contrast to FoxP3<sup>−/−</sup>dKO<sup>het</sup> mice, which developed autoimmune disease and lost body weight, FoxP3<sup>−/−</sup>dKO mice developed no signs of disease and were indistinguishable in their body weight, health, and behavior from normal male mice of the same age (not depicted) or FoxP3<sup>−/−</sup> mice (Fig. 1 B). As an example of their good health, breeding pairs between male FoxP3<sup>−/−</sup>dKO mice and FoxP3<sup>het</sup>dKO females were established, with consequent generation of female mice that were FoxP3<sup>−/−</sup>dKO. Like their male counterparts, these female mice developed and bred normally. We have now maintained a viable colony of FoxP3<sup>−/−</sup>dKO mice for 24 mo, in which breeding pairs have averaged three litters (with a mean of five pups per litter). This contrasts with CD28<sup>−/−</sup> FoxP3<sup>−/−</sup> mice, which develop delayed disease from 90 d, with 50% lethality by 160 d (Singh et al., 2007). From ~8 mo of age, approximately two thirds of the FoxP3<sup>−/−</sup>dKO mice started to develop eczema affecting their ears only but were otherwise healthy with no evidence of abnormal behavior or weight loss. The remaining mice have developed no overt evidence of any abnormality and have survived for 12 mo or more.

FoxP3 is not required for prevention of inflammatory responses to gut microbiota in the absence of OX40 and CD30 signals

In addition to regulating autoimmune T cells, FoxP3 is required for T<sub>reg</sub> cell–mediated counteraction of inflammation against commensal gut microbiota (Izcue et al., 2009). However, FoxP3<sup>−/−</sup>dKO failed to develop any signs of macroscopic or microscopic inflammatory bowel disease, and examination of the lamina propria showed it to be normal (unpublished data), with the exception of a depletion of CD4 T cells similar to that observed in dKO mice (Withers et al., 2009).

Prevention of disease is dependent on both OX40 and CD30

To assess the individual contributions of OX40 and CD30 to autoimmunity in FoxP3<sup>−/−</sup> mice, FoxP3<sup>−/−</sup>dKO female mice were bred with male OX40<sup>−/−</sup> or CD30<sup>−/−</sup> mice. FoxP3<sup>−/−</sup>dKO female mice have two copies of the FoxP3<sup>−/−</sup> allele, all the male offspring of this breeding strategy are FoxP3<sup>−/−</sup> with either a single OX40 (OX40<sup>het</sup>) or CD30 (CD30<sup>het</sup>) gene. Disease onset was delayed in both situations (P = 0.002 for both genes) compared with FoxP3<sup>−/−</sup>dKO<sup>het</sup> mice, clearly demonstrating the relevance of both genes (Fig. 1 A). FoxP3<sup>−/−</sup> mice lacking CD30, but which had a single copy of the OX40 gene (OX40<sup>het</sup>CD30<sup>−/−</sup>), developed severe eczematous skin lesions between 7 and 9 wk and were sacrificed for humane reasons. Disease onset was delayed even further in FoxP3<sup>−/−</sup> mice lacking OX40 but sufficient in a single copy of the CD30 gene (OX40<sup>−/−</sup>CD30<sup>het</sup>; P < 0.001); some developed eczematous skin between 10 and 12 wk without obvious weight loss, indicating an attenuated phenotype compared with FoxP3<sup>−/−</sup>dKO<sup>het</sup> mice (all dead by ~5 wk with 40% body weight loss). This shows that OX40 plays the dominant role but that the contribution of CD30 is significant and acts cooperatively with OX40 to permit the emergence of autoimmune pathology in the context of FoxP3 deficiency.

Abrogation of organ infiltration and high-titer autoantibodies and retention of lymphoid tissue architecture in FoxP3<sup>−/−</sup>dKO mice

To exclude subclinical disease in FoxP3<sup>−/−</sup>dKO mice, animals were sacrificed contemporaneously with FoxP3<sup>−/−</sup>dKO<sup>het</sup>...
littermates that developed overt disease. A striking feature of FoxP3 deficiency is an eczematous skin infiltration by T cells resulting in the scuffy phenotype with infiltration of the subcutaneous tissues of the skin most obvious in the ear macroscopically (Fig. 1 C) but also by microscopy (Fig. 2 A). In contrast, the ears of FoxP3KO dKO mice appeared grossly and microscopically normal and were indistinguishable from WT normal mice. This did not simply reflect a delay in disease onset, as FoxP3KO dKO or FoxP3KO+ dKO mice sacrificed at 180 d also appeared macroscopically and microscopically normal (Fig. S1, A–D). At later time points from 8 mo of age, some FoxP3KO dKO mice developed eczema affecting their ears, but the infiltrates were small and contained few CD4+ T cells (unpublished data). No mice developed fatal autoimmune pathology.

In addition to skin T cell infiltration, at the time of clinical disease onset, FoxP3KO mice develop lymphocyte infiltrations in many other tissues including the liver. These infiltrates form substantial tertiary lymphoid structures in the liver of FoxP3KO/CD30hetOX40het mice with focal aggregates of B220+ B and CD3+ T cells (Fig. 2 B). In contrast, in FoxP3KO dKO mice, there was virtually no infiltration by lymphocytes and certainly no organized aggregates were detected. FoxP3KO dKO mice sacrificed at 6 mo of age also showed a lack of tissue infiltration (Fig. S1 B). After 8 mo, some mice also showed small CD4+ T cell infiltrates in the liver, although ~30% of mice showed no histological evidence of disease. Although liver infiltration was less substantial in OX40het and CD30het FoxP3KO mice, infiltrates were clearly much greater than FoxP3KO dKO mice (Fig. 2 B).

The hallmark of pathogenic human autoimmune antibodies is their high titer and affinity. These autoantibodies also occur in FoxP3KO mice, for example against stomach mouse tissue (Fig. 2 C). Stomach antibodies were also clearly evident in FoxP3KO/OX40het and FoxP3KO/CD30het mice but at minimal low titers in FoxP3KO dKO mice (Fig. 2 C) even when old (not depicted), consistent with our previously reported observations that both CD30 and OX40 are required to generate high-affinity antibodies (Gaspar et al., 2005). Autoantibodies and tissue infiltrates were not observed in FoxP3+ dKO het or FoxP3+ dKO mice (unpublished data).

Compared with normal mice, FoxP3KO dKO het, FoxP3KO/OX40het, and FoxP3KO/CD30het mice exhibited marked lymphadenopathy, and this was significantly but not completely attenuated in FoxP3KO dKO mice (Fig. S1, E and F). Naive CD4 T cells reside exclusively within secondary lymphoid organs like spleen and lymph node (Reinhardt et al., 2001). In FoxP3-deficient human disease, autoimmunity is associated with immunodeficiency within the naive CD4 and also CD8 T cell compartments in lymph nodes and spleen (Costa-Carvalho et al., 2008). Compared with normal mice, FoxP3KO mice had grossly abnormal architecture, with destruction of white pulp areas of both lymph node and spleen (Fig. 2, D and E), and this was associated with gross depletion of CD4+CD62Lhi naive T cells (Fig. 3 A and Fig. S2). In contrast, in FoxP3KO dKO mice the spleen and lymph node architecture was normal, with well organized B and T cell areas (Fig. 2, D and E). Although there was still marked skewing of CD4 T cells to effector/memory phenotype CD62Llo cells, a significant proportion of CD4 T cells were CD62Lhi naive cells. To a lesser extent, naive CD8 T cells were also reduced in
CD30 and OX40 drive autoimmunity in FoxP3 KO mice

CD4 T cells are activated but fail to express IL4 and IFN-γ in FoxP3 dKO mice

Our previous studies have shown that dKO CD4 T cells proliferate just as well as their WT counterparts both in vitro and in vivo (Gaspal et al., 2005), can be induced to express both Th1 and Th2 cytokines under appropriate conditions of stimulation in vivo (Kim et al., 2005), but fail to be sustained as effector/memory cells (Gaspal et al., 2005, 2008). As reported previously by others, FoxP3KO mice have an increased fraction of CD4+CD62LloCD44hi effector/memory cells that express more IL4 and IFN-γ than FoxP3+ mice (Fig. 3 B and Fig. S2). Compared with FoxP3KO dKO het mice, expression of IL4 and IFN-γ in activated FoxP3KO dKO CD4 T cells was substantially reduced and little different from both WT and dKO mice sufficient in FoxP3 (Fig. 3).

In contrast to CD4 T cells, CD8 T cells from FoxP3KO dKO mice were not only highly activated but expressed high levels of IFN-γ compared with FoxP3-sufficient controls. CD8 T cells are implicated in the immunopathology of autoimmune diseases. Therefore, the failure of FoxP3KO dKO CD8 T cells to cause disease suggests that CD8 immune-mediated damage in autoimmune diseases depends on OX40 and CD30 signals to CD4 T cells, or alternatively the potential CD8-mediated damage is much less than for CD4 T cells, confirming previous findings (Blair et al., 1994).

To test directly whether the defect in FoxP3KO dKO CD4 T cells was a result of decreased survival, we transferred neonatal thymocytes, which have been previously shown to transfer disease (Godfrey et al., 1994), from FoxP3KO dKO het or FoxP3KO dKO mice into RAGKO recipients. RAGKO mice that received FoxP3KO dKO het thymocytes developed disease at ~3 wk (Fig. S3 A). Both CD4 (Fig. S3 B) and CD8 (Fig. S3 C) T cells were activated (CD44hiCD62Llo) and a high proportion of both CD4 and CD8 T cells expressed IFN-γ (Fig. S3, B and C). RAGKO mice injected with FoxP3KO dKO or FoxP3+ dKO het thymocytes did not get sick. These mice were culled after 10 wk and their T lymphocytes analyzed. Although all the CD4 T cells were CD44hiCD62Llo (Fig. S3 B), far fewer CD4 cells (P < 0.05) were recovered from mice that received FoxP3KO dKO thymocytes compared with FoxP3KO dKO het or FoxP3+ dKO het thymocytes, and very few of these cells expressed IFN-γ (Fig. S3 D; P < 0.05). CD8 T cell numbers were also reduced, but the reduction was much less than for CD4 T cells, although the expression of IFN-γ was significantly less (P < 0.05; Fig. S3 D).

Blocking antibodies to OX40L and CD30L abrogate disease mediated by FoxP3KO T cells

To exclude effects of OX40 and CD30 on T cell development and to test whether in vivo blockade of OX40 and CD30 signals might be effective in treating autoimmune disease, 107 FoxP3KO dKO het thymocytes were transferred into RAGKO mice. After transfer, mice received either twice weekly injections of blocking mAbs to OX40 and CD30 ligands (Akiba et al., 2000) or control rat IgG (see Materials and methods). Mice that received control rat IgG developed signs of FoxP3KO disease at ~3 wk after transfer, whereas mice treated with blocking mAbs looked healthy at this time and remained healthy for several weeks even after blocking mAbs were stopped (Fig. 4 A). FACS analysis of these mice sacrificed at the same time as sick mice showed that they had reduced numbers of CD4+ T cells, and much reduced expression of IFN-γ.
similar to that observed for FoxP3KO dKO thymocyte transfers (Fig. 4, B and C). Analysis of liver tissue in mice injected with blocking mAbs also showed that T cell infiltrates were much reduced (unpublished data). We do not think these mAbs are simply depleting cells that express these molecules, as lymphoid tissue inducer cells that express high levels of OX40 and CD30 ligands (Kim et al., 2003) are not depleted by these mAbs (unpublished data).

To exclude effects of OX40 and CD30 on T cell activation, treatment with blocking mAbs was delayed for 8 d to allow FoxP3KO KO T cells to be fully activated. At this time point after transfer, FACS analysis of splenocytes showed that all transferred CD4 T cells were CD44hi and most were CD62Llo (Fig. S4). Injection of blocking mAbs from this time point again prevented disease onset in remaining RAGKO mice that received FoxP3KO thymocytes (Fig. 4 D).

We have previously shown that OX40 and CD30 signals are essential for the generation of CD4 memory antibody responses in mice (Gaspal et al., 2005). In this paper, we show that these signals, particularly the former, are required for the immunopathology driven by Th1 and Th2 FoxP3-deficient autoimmune effector CD4 T cells. The absence of lethal disease with minimal tissue infiltration in FoxP3KO mice lacking OX40 and CD30 demonstrates that these signals are crucial for effector CD4 T cell–driven autoimmune tissue damage. Molecular phylogeny shows that the TNF ligands for OX40 and CD30 evolved late (Glenney and Wiens, 2007), as orthologs of these genes are present only in mammals and birds (www.ensembl.org), which like mammals can develop spontaneous autoimmune disease (Wick et al., 2006). In contrast, there is little or no evidence that lower vertebrates lacking these genes develop autoimmune disease (Wick et al., 2006). In contrast, there is little or no evidence that lower vertebrates lacking these genes are susceptible to autoimmune disease (Wick et al., 2006). In contrast, there is little or no evidence that lower vertebrates lacking these genes spontaneously develop clinically relevant autoimmunity. In addition to suppressing autoimmunity, FoxP3-dependent Treg cells prevent inflammatory responses to food and commensal microbiota in the gut (Izcue et al., 2009). However, in the absence of OX40 and CD30, there is no evidence of gut inflammation in the absence of Treg cells.

Therapeutic trials of anti-OX40 ligand mAbs are already in human clinical trials for asthma (Clinical Trials NCT00983658). This study highlights the crucial importance of both OX40 and CD30 cells in mediating tissue damage in human autoimmune diseases mediated by pathogenic CD4 T cells and suggests that strategies that block both pathways would act synergistically to prevent this damage occurring. In support of this, we showed that injection of blocking antibodies to OX40 and CD30 ligands could also prevent disease onset in an adoptive transfer model of FoxP3KO disease, emphasizing the potential therapeutic role in human autoimmune disease.

**MATERIALS AND METHODS**

**Mice.** All experiments on animals were approved by Birmingham University local ethical panel review and UK Home office guidelines. Animals were bred in accordance with home office guidelines at the University of Birmingham, Biomedical Services Unit. Heterozygous FoxP3+/- females were provided by A. Rudensky (Howard Hughes Medical Institute and Immunology Program, Memorial Sloan-Kettering Cancer Center, New York, NY) and were crossed with CD30KO/OX40KO (dKO) or mice deficient in OX40 (OX40-/-) or CD30 (CD30-/-).

**Thymocyte transfer.** Approximately 10 x 10^6 FoxP3KO thymocytes from newborn (day 2–5) male FoxP3KO mice were injected i.v. into RAGKO mice to transfer FoxP3KO disease.

**Blocking antibody injection.** Blocking mAbs against mouse OX40L (clone RM134L) and CD30L (clone RM153) were prepared as described previously (Akiba et al., 2000). Control rat IgG was purchased from Sigma-Aldrich. Mice were twice weekly injected with either 0.5 mg anti-OX40L and 0.5 mg anti-CD30L mAbs or 1 mg of control IgG.

**Immunofluorescence microscopy.** 5-µM frozen tissue cryostat sections were stained with fluorescent antibodies as described previously (Kim et al., 2003). Liver sections were pretreated with avidin/biotin blocking reagents (Sigma-Aldrich). Primary anti–mouse antibodies used were: anti-B220 biotin (clone RA3-6B2; eBioscience), anti-CD3 FITC and biotin (145-2C11; BD), anti-CD4 Alexa Fluor 647 (GK1.5; eBioscience), anti-CD11c biotin (N418; eBioscience), anti-IgM rhodamine red (Jackson ImmunoResearch Laboratories, Inc.), CD4–Alexa Fluor 647 (clone L3T4), and anti-FoxP3 FITC (FJK-16s). Biotinylated Abs were detected with streptavidin–Alexa Fluor 555 or streptavidin–Alexa Fluor 647 (Invitrogen). FITC-conjugated Abs were detected using rabbit anti-rabbit IgG-FITC (Jackson ImmunoResearch Laboratories, Inc.). For primary antibody reactions, sections were incubated with biotin–streptavidin complexes followed by streptavidin–Alexa Fluor 555 or streptavidin–Alexa Fluor 647. Stained sections were counterstained with 4′,6-diamidino-2-phenylindole and mounted with anti-fade reagents (Invitrogen). Immunofluorescence images were acquired with an Axiovert 35 microscope equipped with a Zeiss Plan-Neofluar 63x/1.4 Oil or 100x/1.3 Oil objective (Carl Zeiss; Thornwood, NY) and Axiosimager M2 with a cooled charged-coupled device camera (AxioCam HRm; Carl Zeiss). Images were analyzed using Fiji software. Analyzed data were plotted using Microsoft Excel. Statistical differences were determined using Student’s t test (GraphPad, San Diego, CA). Values of *P < 0.02* were considered statistically significant.
anti-FITC Abs (Invitrogen) and then goat anti–rabbit FITC Abs (Southern-Biotech). IgG autoantibodies were detected by adding sera (diluted 1/40 in 1% BSA/PBS) to RAG cdKO stomach sections followed by goat anti–mouse IgG Alexa Fluor 594 (Invitrogen). Sections were counterstained with DAPI (Invitrogen) and mounted using DABCO (Sigma-Aldrich).

FACS and intracellular cytokine staining. Splenocytes prepared from the indicated mice were restimulated in vitro for 4 h at 37°C in the presence of Golgistop (BD) on plates coated with 5 μg/ml anti-CD3 Ab and 0.5 μg/ml of soluble anti-CD28 Ab (BD). Cells were then surface stained with anti-CD3 FITC, CD62L PE, CD8 PE Texas red, CD4 PE-Cy5.5, and CD44 PE-Cy7 (EBioscience) and then fixed and permeabilized with Cytofix/Cytoperm Plus (BD) according to the manufacturer’s instructions. Intracellular cytokine expression was revealed by staining permeabilized cells with APC-conjugated mAb to IFN-γ and IL4 (BD).

Statistics. Mann–Whitney nonparametric statistics were used throughout to analyze the significance of differences between groups of mice.

Online supplemental material. Fig. S1 shows confocal micrographs of cryostat tissue sections from Foxp3 cdKO mice aged 6 mo. Fig. S2 shows CD4 T cell number and activation status in Foxp3 cdKO mice. Fig. S3 shows that RAG cdKO mice injected with Foxp3 cdKO thymocytes do not develop disease. Fig. S4 shows activation status of Foxp3 cdKO CD4 T cells 8 d after transfer into RAG cdKO hosts compared with CD4+ T cells from WT C57BL/6 spleen. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20101484/DC1.

We are grateful to Dr. Alexander Rudensky for permission to use FoxP3-deficient mice.
