Hematopoietic stem cells (HSCs) emerge from aortic endothelium via the endothelial-to-hematopoietic transition (EHT). The molecular mechanisms that initiate and regulate EHT remain poorly understood. Here, we show that adenosine signaling regulates hematopoietic stem and progenitor cell (HSPC) development in zebrafish embryos. The adenosine receptor A2b is expressed in the vascular endothelium before HSPC emergence. Elevated adenosine levels increased runx1/cmyb+ HSPCs in the dorsal aorta, whereas blocking the adenosine pathway decreased HSPCs. Knockdown of A2b adenosine receptor disrupted scl+ hemogenic vascular endothelium and the subsequent EHT process. A2b adenosine receptor activation induced CXCL8 via cAMP–protein kinase A (PKA) and mediated hematopoiesis. We further show that adenosine increased multipotent progenitors in a mouse embryonic stem cell colony-forming assay and in embryonic day 10.5 aorta-gonad-mesonephros explants. Our results demonstrate that adenosine signaling plays an evolutionary conserved role in the first steps of HSPC formation in vertebrates.
gata2, and sox17 also regulate different steps in this developmental transition (Tsai et al., 1994; Porcher et al., 1996; Kim et al., 2007). Hematopoietic transcription factors are activated by extrinsic signals. Growth factors and morphogens such as bone morphogenetic protein 4 (BMP4), Notch, Hedgehog, FGF, Wnt, and vascular endothelial growth factor (VEGF), from the surrounding endothelial or mesenchymal cells, control the hematopoietic program (for review see Kaimakis et al., 2013).

One group of factors that may participate in the induction of HSCs is purinergic signals. Purines (such as adenosine, ADP, and ATP) exhibit specific extracellular signaling activity in the regulation of many diverse functions including auto-regulation of blood flow, cell proliferation and differentiation, and stem cell regeneration (Glaser et al., 2012; Rossi et al., 2012). Many of these functions act through cell surface receptors (Rossi et al., 2012). Extracellular adenosine is hydrolyzed from ATP by ectonucleotidases, and its level is elevated as oxygen supply decreases or energy demand increases (Haskó et al., 2008). Adenosine acts at four distinct G-protein–coupled receptors (A1 and A3 adenylyl cyclase–inhibitory and A2a and A2b adenylyl cyclase–stimulatory receptors; for review see Koupnova et al., 2012) and has been shown to regulate early development, such as modulating embryo cardiac function via the A1 receptor (Funakoshi et al., 2006). Accumulating evidence also suggests that adenosine signaling has a role in hematopoietic cells. Adenosine signaling induces the proliferation and differentiation of hematopoietic progenitor cells in the lymph gland of Drosophila melanogaster embryos (Mondal et al., 2011). In the adult mice, administration of drugs that elevate extracellular adenosine levels increases hematopoietic spleen colony formation in sublethally gamma-irradiated animals (Hofer et al., 1997) and enhances cell cycling of hematopoietic progenitor cells (Pospisil et al., 2001). These observations together indicate a potential role of adenosine in regulating HSCs.

In zebrafish, nuxt1– and cmyb–expressing hematopoietic stem and progenitor cells (HSPCs) first appear along the ventral wall of the dorsal aorta (functionally equivalent to AGM in mice). These HSPCs will later colonize the caudal hematopoietic tissues (CHT; equivalent to mouse fetal liver) and eventually reside in definitive hematopoietic organs, the thymus and kidney marrow (Chen and Zon, 2009). Through an in vivo screening approach, we identified the adenosine signaling pathway: [2-chloro-N6–iodobenzyl]adenosine–5′–N–methylcarboxamidé (Chloro-IB-MECA), (2S)–N6–[2–endo-Norbornyl]adenosine ((S)–ENBA; adenosine receptor agonists), and erythro-9–(2–Hydroxy–3–nonyl)adenine (EHNA) hydrochloride (an adenosine deaminase inhibitor). Follow-up live-imaging experiments revealed that the increased HSPCs in the CHT after adenosine treatment came from more production in the AGM (not depicted). This observation prompted us to examine the role of adenosine in AGM HSPC formation.

We treated wild-type embryos with different adenosine analogues (including the screen hits) and examined their effect on HSC development in the ventral wall of dorsal aorta. Among the chemicals tested, the most potent enhancer is 5′–N–ethylcarboxamidoadenosine (NECA), a robust adenosine receptor agonist, with preference toward A2-type adenosine receptors. As shown in Fig. 1, NECA significantly increased nuxt1/cmyb expression (Fig. 1, A–B′). Conversely, CGS15943, a potent adenosine receptor nonselective antagonist, decreased nuxt1/cmyb HSPCs (Fig. 1, C and C′). The effect of these chemicals on hematopoiesis was dose dependent and most potent when continuously treating the embryos from early somitogenesis (5-somite stage) to 36 hpf. It is known that adenosine signaling plays a role in cardiovascular function (Haskó et al., 2008), so we examined whether exposure to adenosine analogues altered vascular formation or blood circulation, but they appeared normal at the stages we studied (Fig. 1, E′–G′; and not depicted).

To examine whether the effect of adenosine is to increase the expression of HSPC genes or the number of HSPCs, we added an adenosine receptor agonist and antagonist to Tg(cmyb; eGFP; flk1:tdmcherry) embryos, in which HSCs and progenitors are marked by coexpression of both fluorescent proteins (Yue et al., 2012). We found that the number of HSPCs in these embryos was significantly increased after NECA treatment (4.4 ± 0.4/somite vs. 3.6 ± 0.2/somite [con]) and significantly decreased after CGS15943 exposure (3.0 ± 0.2/somite; Fig. 1, D–H). These data indicate that adenosine increases HSPC numbers rather than acting on gene expression alone. Therefore, adenosine regulates definitive hematopoiesis during development, and likely via an effect on an adenosine receptor.

Adenosine–regulated HSPC formation is primarily through A2b adenosine receptor

Adenosine signaling exerts its effect by activating G protein–coupled receptors on target cells. Four adenosine receptors,
A$_1$, A$_2$, A$_{2a}$, A$_{2b}$, and A$_3$ have been identified. Each receptor has a distinct cellular and tissue distribution and modulates different biological functions (Haskó et al., 2008). We focused on A$_{2a}$ and A$_{2b}$ adenosine receptors (denoted here as A$_{2a}$ and A$_{2b}$) because of their enrichment in endothelial and hematopoietic cells (Adair, 2005; Rossi et al., 2012) and because of the

Figure 1. An adenosine analogue regulates definitive hematopoiesis. (A–C’) In situ hybridization of runx1/cmyb at 36 hpf. Representative images of wild-type embryos treated with DMSO (A and A’), adenosine receptor agonist NECA (20 µM; B and B’), and antagonist (10 µM CGS15943; C and C’). Prime panels depict the AGM region of the embryos in A–C (red arrows). The numbers at the right corner (here and following) indicate embryos with altered HSPC staining over the total number of embryos examined. (D) Bright view of Tg(cmyb;GFP, flk1:mcherry) embryos. The square indicates the live-imaging position. (E–G’) Confocal images of double-transgenic embryos at 36 hpf. The embryos were treated with DMSO (E and E’), NECA (F and F’), or CGS15943 (G and G’). The white arrows point to the double-positive HSPCs in the aorta region. The blue arrowheads point to the multiciliate cells of the pronephros. Dashed lines indicate the somite boundaries. (H) Quantification of the number of HSPCs per somite in Tg(cmyb;GFP, flk1:mcherry) embryos at 36 hpf. The results are presented as mean ± SE (Student’s t test: *, P < 0.05; n = 5–8 per group). Bars, 100 µm.
During embryo development, A2b is predominantly expressed in the vasculature within the AGM and CHT (Fig. 2, A and B), which is consistent with the previous findings (Boehmler et al., 2009). Real-time quantitative PCR (qPCR) above-described effect of NECA (an A2-type adenosine receptor agonist). We designed morpholinos (MOs) to knock down the two receptors and identified A2b as an important player in HSC development.
that circulation is required to maintain A2b expression, but not for induction of expression.

We used a translation-blocking MO and a splice MO to block the A2b receptor. We confirmed that the splicing MO inhibits A2b splicing (Fig. 2 E). Knockdown of A2b, using either MO did not affect the general development of the embryos (not depicted) but caused a strong reduction of runx1/cmyb in the AGM (Fig. 2, F, G, L, and M). Injection of zebrafish A2b mRNA rescued the expression of runx1/cmyb in A2b splicing MO-injected embryos (Fig. 2, N and O), and injection of human A2b mRNA partially rescued runx1/cmyb in the embryos injected with A2b translation-blocking MO (Fig. 2, H, I, and S), which supports the specificity of MO targeting. In addition, we injected A2b MO into p53−/− mutant embryos to attenuate the off-target effect (Robu et al., 2007), and we saw similar phenotypes in p53 mutant embryos (not depicted), which also supports that the observed HSPC defects are caused by specific loss of A2b function. The robust phenotype after blocking A2b function prompted us to examine the effect of an A2b receptor selective agonist (BAY 60-6583; Koupenova et al., 2012) in zebrafish embryos. As expected, BAY 60-6583 significantly increased the expression of runx1/cmyb (Fig. 2, J and K).

Consistent with the runx1/cmyb staining, knockdown of A2b in Tg(cmyb:GFP, flk1:mcherry) reduced the double fluorescent-labeled HSPCs (1.1 ± 0.2/somite vs. 3.6 ± 0.6/somite [conj]). BAY 60-6583 treatment increased the number of HSPCs in the Tg(cmyb:GFP, flk1:mcherry) embryos (4.6 ± 0.3/somite; Fig. 2, P–R and T). Alterations of adenosine signaling with either treatment did not have an effect on the GFP-labeled cells in the pharynx (Fig. 2, P–R).

Compared with cmyb, runx1 is more specifically expressed in nascent HSCs. We examined embryos using runx1 probe alone and found that knockdown of A2b strongly reduced runx1+ cells (Fig. 3, A and B). We also studied hematopoiesis and subsequent lineage differentiation at later time points after A2b inhibition. A2b morphants strongly reduced runx1+ HSPCs in the CHT at 60 hpf (Fig. 3, C and D), reduced cmyb+ multipotent progenitor cells in the CHT at 4.5 d post-fertilization (dpf; Fig. 3, E and F), and reduced rag1+ thymic T cells (Fig. 3, G and H). Together, our results indicate that A2b regulates HSPC development.

To determine the specificity of loss of A2b–induced HSPC defects, we examined the development of other tissues. A2b morphant embryos demonstrated normal heart beating and circulation (not depicted). Those embryos developed normal vasculature differentiation, as shown by the normal expression of flk1:mcherry (Fig. 2, P′–Q′), the vessel marker flk1, the artery marker EphB2, and the normal intersegment vessels (flk1 and flk1:mcherry), pronephros (cd1h17), and somite (myoD; Fig. 3, I–P). In addition, A2b MO–injected embryos showed normal primitive erythroid cells (gata1) and angioblasts (sd; Fig. 3, Q–T). The transient expression of cmyb and runx1 in early somite–stage embryos was not affected (Fig. 3, U–X). These results support that the defects in HSPC specification in the absence of A2b are highly specific, not caused by defects from the nearby tissues.

Adenosine promotes hematopoietic development in mESC culture and in mouse AGM explant

To test whether adenosine signaling would have an effect on mammalian hematopoiesis, we assessed the effect of adenosine on the development of mouse HSPC populations. We first used an mESC hematopoietic differentiation system, an accessible in vitro model which recapitulates mouse embryonic hematopoiesis (Kim et al., 2013). In this model, mESCs are aggregated into embryoid bodies (EBs) and differentiated into primitive streak-like mesoderm on day 2, hemangioblasts on day 3.25, and hematopoietic precursors after day 5. A2b receptor is present between days 0 and 6 of EB differentiation (not depicted). Analysis of gene expression data in sorted populations from day 6 EBs (Kim et al., 2013) showed that A2b is highly in the VE-cadherin+CD41+ endothelial cells and low in the CD41+ populations (Fig. 4 A), indicating that A2b likely regulates VE-cadherin+ cell intermediates, a fraction from which HSCs emerge. Methylcellulose-based colony-forming assay was performed to measure both hematopoietic progenitor types and numbers. Addition of A2b selective agonist BAY 60-6583 to EBs between days 4 and 6 significantly increased the number of hematopoietic colonies, including definitive erythroid (CFU-E), granulocyte/monocyte (CFU-GM), and multipotent granulocyte/erythrocyte/macrophage (CFU-E/GM/GEMM) colonies, at a concentration of 0.5–2.5 µM (Fig. 4 B). Consistently, qPCR analysis revealed that many hematopoietic genes, including sd, lmo2, runx1, gata1, bH1, and Bmajor (adult globin), were up-regulated on day 6 after BAY 60-6583 treatment (Fig. 4 C). In contrast, BAY 60-6583 did not increase the expression of the mesoderm marker Cerberus, the expression of endothelial gene fli1 (Fig. 4 D). Interestingly, the expression of fli1 was decreased after BAY 60-6583 treatment (Fig. 4 D), consistent with the previous study showing the antagonist effect of runx1 on fli1 (Swiers et al., 2013). These data support a positive role of adenosine and its A2b receptor in regulating mESC hematopoietic differentiation.

Next, we examined whether BAY 60-6583 promotes HSCs in the mouse AGM. A recent study performed expression profiling of the AGM HE at the onset of circulation (Swiers et al., 2013). We analyzed the microarray data and found that A2b expression is high in HE and low in non-HE and hematopoietic progenitors (Fig. 4 E), similar to A2b expression from day 6 EBs. We confirmed A2b expression in VE-Cadherin+ cells from the E10.5 AGM by RT-PCR (Fig. 4 F). To test the effect of adenosine signaling on AGM HSPCs, AGM explants from E10.5 embryos were cultured with DMSO or BAY 60-6583, and HSC activity was measured by CFU...
culture (CFU-C) assay. As shown in Fig. 4 G, the addition of BAY 60-6583 significantly increased the numbers of erythroid, granulocyte/macrophage (GM), and multipotent progenitor (GEMM) colonies. Thus, adenosine promotes AGM HSCs in mouse.

Adenosine is required for the EHT

It is known that HSCs originate from HE via EHT. Recent time-lapse imaging studies have directly captured the emergence of HSPCs from flk1:GFP+ aortic endothelial cells in live zebrafish embryos (Bertrand et al., 2010; Kissa and Herbomel, 2010). To examine whether adenosine regulates the EHT, we injected A2b MO into Tg(flk1:GFP) embryos and used time-lapse imaging to track the formation of HSPCs between 32 and 60 hpf, as previously described (Kissa and Herbomel, 2010). As shown in Fig. 5 and Videos 1 and 2, in A2b-deficient embryos, flk1:GFP+ endothelial cells initiated bending, and sometimes contraction, normally, albeit more rarely than in control embryos. We noticed that as the flk1:GFP+ cells rounded up to become HSCs, a subset of these cells burst into small cellular pieces (Fig. 5, A–C). The bursting is very similar to the events seen in runx1-deficient embryos, in which the EHT event of flk1:GFP+ cells aborts into cell death (Kissa and Herbomel, 2010). These results suggested that adenosine signaling is required to achieve successful EHT.

To explore the relationship between adenosine signaling and runx1, we used an inducible runx1 Tg line (hsp70:runx1). After heat shock induction, runx1 was expressed throughout the embryo (Fig. 5 D) and slightly increased the definitive hematopoietic marker cmyb in control embryos (Fig. 5, E and F). In A2b

---

**Figure 3. Adenosine signaling through A2b specifically regulates HSPC development.** (A–H) Control or A2b MO-injected embryos stained for runx1 in the AGM at 36 hpf (A and B), runx1/cmyb in the CHT at 60 hpf (C and D), cmyb in the CHT (E and F), and RAG1 in the thymus (red arrows in G and H) at 4.5 dpf. (I–X) Control or A2b MO-injected embryos stained for vasculature (flk1; I and J), dorsal aorta (ephrinB2; K and L), pronephros (cdh17; M and N), and somite (myoD; O and P), primitive hematopoiesis (gata1 and scf; Q–T), and cmyb and runx1 (U–X) at the developmental stages indicated. In I and J, red arrowheads mark intersegment staining. Bars, 100 µm.
Article

MO–injected embryos, overexpression of runx1 showed a partial, but statistically significant rescue of cmyb staining (Fig. 5, G–I). Thus, overexpressing runx1 rescued HSPC formation in the absence of A2b, suggesting that runx1 acts downstream of A2b.

**Adenosine signaling regulates scl**

The abortive EHT of flk1:GFP cells could result from a lack of hemogenic potential in these cells. We then examined whether adenosine regulates HE specification, the onset of EHT. The master hematopoietic transcriptional regulator scl is critical for establishing the hemopoietic potential in aorta endothelial cells and plays its role before runx1 during definitive hematopoiesis. In zebrafish, an N-terminal truncated scl-B isoform is essential for HSPC emergence. The scl reporter line Tg(scl: d2eGFP) marks the hemogenic vascular endothelium, which is later transformed to HSPCs via EHT (Zhen et al., 2013). In the absence of A2b, scl-B-GFP+ HE cell population was strongly reduced (1.6 ± 0.2/somite vs. 3.5 ± 0.3/somite [con]; Fig. 6, A–B and H). Addition of A2b receptor agonist BAY 60-6583 to wild-type embryos increased the number of scl-B-GFP+ in the AGM (4.6 ± 0.7/somite vs. 3.5 ± 0.5/somite [con]; Fig. 6, C, C′, and H). Overexpression of scl mRNA in zebrafish embryos partially rescued runx1+/cmyb+ HSPCs in A2b-deficient embryos (Fig. 6, D–G and I). These results indicate that adenosine signaling mediates scl+ hemogenic vascular endothelium. Together, our data suggest that adenosine mediates HSPC formation via regulation of hematopoietic commitment of endothelial cells.

These results indicate that adenosine signaling mediates scl+ hemogenic vascular endothelium. Together, our data suggest that adenosine mediates HSPC formation via regulation of hematopoietic commitment of endothelial cells.
Figure 5. Adenosine signaling is required for EHT in zebrafish. (A and B) Still images from in vivo time-lapse confocal imaging of Tg(flk:GFP) embryos between 32 and 48 hpf. Embryos are either uninjected (A) or injected with A2b MO (B). Numbers indicate recording time in hours and minutes. Arrows in A point to three aorta cells undergoing successful EHT. Cells 2a and 2b are the daughter cells of cell 2. The two dorsal aorta cells 1' and 2' in B initiate EHT and burst into pieces (marked by circles). (C) Quantification of the number of flk:GFP+ cells per somite undergoing burst during the 16-h time-lapse period. The results are presented as mean ± SE (Student’s t test: **, P < 0.01; n = 6–8 embryos per group). (D) Tg(hsp70:runx1) embryos stained for runx1 without heat shock (HS) induction or after heat shock induction. (E–H) Expression of cmyb at 36 hpf in Tg(hsp70:runx1) embryos. Embryos were either uninjected (E and F) or injected with A2b MO (G and H). Embryos either received no heat shock treatment (E and G) or received heat shock induction (F and H).
Adenosine regulates CXCL8 production and mediates hematopoiesis via CXCL8

In many cell types, adenosine promotes the production of cytokines, chemokines, and growth factors and often exerts its cellular effects through or in association with these factors (Adair, 2005). In vascular endothelial cells, A<sub>2b</sub> activation modulates the production of several angiocrine factors (Feoktistov et al., 2002). One of the major factors is CXCL8 (also known as IL-8). CXCL8 is known as a potent stem cell–mobilizing agent (Laterveer et al., 1995), and it also increases the proliferation of hematopoietic progenitor cells in vitro (Hermouet et al., 2000). Human aortic endothelial cells (HAECs) express the A<sub>2b</sub> receptor (Iwamoto et al., 1994), and we confirmed A<sub>2b</sub> expression by RT-PCR (not depicted). We treated HAECs with BAY 60-6583, which increased CXCL8 protein production (Fig. 7 A). To demonstrate that A<sub>2b</sub> regulates CXCL8 in zebrafish embryos, we examined cxcl8 transcripts. Knockdown of A<sub>2b</sub> strongly decreased cxcl8 expression in flk1:GFP<sup>+</sup> endothelial cells, but did not affect the expression of endothelial marker flk1 (Fig. 7 B). We next examined the function of CXCL8 in HSC development. Inhibition of cxcl8 with MO (Stoll et al., 2011) in zebrafish embryos strongly reduced runx1/<i>cmyb</i><sup>+</sup> HSPCs in the AGM (Fig. 7, C–F) and the CHT (Fig. 7, I and J). Loss of CXCL8 did not have an effect on the development of the dorsal aorta at the time when HSPCs start to emerge (Fig. 7, K and L) and did not interfere with primitive hematopoiesis (not depicted), which supports a specific role of cxcl8 in HSPC formation. In addition, we generated a CXCL8 mutation by a transcription activator–like effector nuclease (TALEN) approach. This mutation...
Adenosine regulates HSC formation via cAMP–PKA

A<sub>2b</sub> receptor is commonly coupled to adenylyl cyclase via G protein subunit Gs and increases intracellular cAMP that activates PKA (Fredholm, 2007). We treated HAECs with BAY 60–6583 and performed chemiluminescence assay for cAMP activity. BAY 60-6583 induced cAMP production (Fig. 8 A). In addition, treatment of HAECs with H89 reduced BAY 60-6583–induced CXCL8 production (Fig. 8 B). To examine the role of cAMP in A2b-mediated hematopoietic induction in embryos, we applied H89 to zebrafish embryos. H89 at 1 µM decreased runx1<sup>+</sup>/cmyb<sup>+</sup> HSPCs in the wild-type embryos and abolished the enhancement effect of NECA on leads to the deletion of two amino acids in the conserved CXC domain (Fig. 7 M; Fernandez and Lolis, 2002), which has been shown to be important for its tertiary structure. We found that the HSPC staining is reduced in CXCL8 mutant embryos (Fig. 7, N and O), in accordance with the defects we observed in CXCL8 MO knockdown embryos. Similar to loss of A<sub>2b</sub>, loss of CXCL8 also reduced scl<sup>+</sup> hemogenic vascular endothelium (Fig. 7, P–R). More importantly, cxcl8 mRNA restored HSCs and progenitors in the embryos that lack the A<sub>2b</sub> (Fig. 7, G and H). These results suggest that adenosine signaling regulates CXCL8 production to mediate HSPC development.
scl+ hemogenic vascular endothelium (Fig. 8, K–M). These data support that cAMP–PKA acts downstream of A2b in promoting HSPC emergence.

Overall, these data indicate that adenosine signaling through A2b in endothelial cells activates the cAMP–PKA pathway, which up-regulates the production of cytokine CXCL8. In HSPCs (Fig. 8, C–F). We also applied forskolin, an activator of adenyl cyclase commonly used to raise levels of cAMP, to A2b MO-injected embryos. At 1 µM, forskolin increased runx1/cmyb staining in the wild-type embryos and partially restored runx1/cmyb+ HSPCs in A2b-deficient embryos (Fig. 8, G–J). In addition, inhibition of PKA activity with H89 reduced...
In the developing embryo, HSPCs derive from HE, a crucial intermediate population generated from endothelial cells. However, the signaling pathways that induce the hemogenic commitment of endothelial cells remain largely unknown. sl is one of the early molecular determinants for HE (Lancrin et al., 2009). But little is known regarding how an sl event is regulated. Our experiments demonstrate that adenosine $A_2b$ is expressed in vascular endothelial cells in zebrafish embryos and that CXCL8 promotes the emergence of HSPCs from sl-marked HE in mouse AGM. Adenosine signaling modulates sl-mediated hemopoietic commitment from aortic endothelium.

It is well known that adenosine stimulates the production of multiple growth factors and cytokines (Foeksttov and Biaggoni, 2011). In the AGM, endothelial cells are a probable source of the environmental factors that could affect HSC specification. We show that adenosine regulates CXCL8 production in the vascular endothelial cells. CXCL8 is often associated with neutrophil chemotaxis (Bagnolino and Clark-Lewis, 1992). It also has other cellular functions such as inducing rapid mobilization of HSCs in rodents (Latveer et al., 1995). But its role during developmental hematopoiesis remains unexplored. We demonstrate that CXCL8 regulates sl+ HE and subsequent HSPC development during embryogenesis, similar to adenosine $A_2b$. Moreover, cxcl8 restores HSPC formation in $A_2b-$deficient embryos. Although adenosine may induce hematopoiesis through additional growth factors, our data suggest that adenosine acts at least partly through stimulating CXCL8 to promote HE and HSPC specification.

In addition, we show that CAMPKA is a downstream effector of adenosine signaling, and it underlies adenosine-induced CXCL8 production in endothelial cells, which is consistent with a previous report that the CXCL8 gene promoter has a cAMP-responsive element (CRE)–like site (Iourgenko et al., 2003). An accompanying study in this issue by Kim et al. demonstrated that shear stress activates the PKA–CREB pathway in VE-cadherin$^+$ cells, which promotes AGM HSC emergence. Recent studies indicate that shear stress can lead to the release of ATP, which is quickly converted to adenosine (Yegutkin et al., 2000; Wen et al., 2011). In our study, we found that the expression of $A_2b$ in vascular endothelial cells is maintained by blood flow. Therefore, it is possible that during HSC development, shear stress induces adenosine release, and its effect via $A_2b$ contributes to the activation of the CAMPKA pathway in endothelial cells. We propose that CAMPKA–CREB regulates the production of growth factors and cytokines, which in turn promotes HSPC development controlled by a transcriptional program. It is also possible that CAMPKA–CREB may directly regulate sl and CXCL8 and other factors may act to reinforce the transcriptional program. In any case, our experiments together highlight the critical role of the CAMPKA signaling pathway during vertebrate HSPC emergence.

It remains unknown how CXCL8 regulates HSPC emergence. Since it has been suggested that CXCL8 enhances cell growth and survival in different types of cells (Hermouet et al., 2000), it is possible that CXCL8 production in the AGM microenvironment affects the survival and/or proliferation of newly formed sl+ hemogenic endothelial cells and HSPCs. We found that CXCL8 receptors cxr1 and cxr2 are expressed in flk1$^+$ vascular endothelial cells in zebrafish embryos before HSPC emergence (unpublished data), which supports an autocrine signaling of CXCL8. The precise mechanism underlying CXCL8-mediated HSPC induction awaits further study.

In addition to acting in the formation of HE, our time-lapse imaging experiments suggest that adenosine might also regulate the transition of endothelial cells to hematopoietic cells. runx1 is a central factor critical for the generation of HSCs from HE. It has been suggested that sl might activate runx1, directly or indirectly, to promote the conversion of endothelial cells to hematopoietic cells. In zebrafish embryos that lack runx1, sl$^+$ HE remains intact (Zhen et al., 2013). In $A_2b$- and CXCL8-deficient embryos, runx1 expression was decreased, and sl-marked hemogenic endothelial cells were also reduced. Our data support that the $A_2b$–CXCL8 axis acts upstream of sl rather than runx1. It is intriguing that we found that overexpression of runx1 restored HSPCs in $A_2b$-deficient embryos. This finding supports the idea that overexpression of runx1 may bypass the requirement of sl-induced hematopoietic potential in endothelium.

Collectively, our experiments have discovered that adenosine regulates the generation of HSPCs in the early embryo. We provide evidence that it acts through $A_2b$ in endothelial cells to regulate HE and subsequent HSPC emergence, partly through up-regulation of CXCL8. These results provide novel insights into the signaling pathways that will be needed to derive HSCs from ESCs or pluripotent cells.

**MATERIALS AND METHODS**

**Animals.** Mice and zebrafish were maintained at Boston Children’s Hospital according to institutional animal care and use committee protocols. The zebrafish wild-type Tubingen and transgenic lines flk1:GFP, flk1:mycerry, Myh9:GFP, aldB:de2GFP (Z. Wen, Hong Kong University of Science and Technology, Hong Kong, China), and p53$^{-/-}$ were used in this study.
**Embryo chemical treatment.** Wild-type and transgene embryos were treated from 5-somites to 36 hpf. 20–50 µM NECA, 10–20 µM CGS19543, and 5–10 µM BAY 60-6583 were obtained from Tocris Bioscience. **Confocal imaging.** Live embryos were anesthetized in 0.04 mg/ml Tricaine, mounted in 1% low-melting agarose, and imaged with a Leica confocal microscope. Apf/Flk* cells were counted in projections of z-stack images (n = 5–10 embryos per group). **In situ hybridization.** In situ hybridization was performed as previously described (Thisse and Thisse, 2008). The images were taken with a Leica stereomicroscope and processed using Adobe Photoshop. **FACS sort cells and qPCR analysis.** Flk1-GFP embryos were manually dissociated with 0.9% PBS containing Liberase (Sigma-Aldrich). GFP* cells were sorted into LS-TRiZol (Sigma-Aldrich). Total mRNA was extracted according to the manufacturer’s protocol. Genomic DNA was removed using TURBO DNA-free kit (Life Technologies). cDNA was synthesized using SuperScript First-Strand synthesis system (Life Technologies); qPCR was performed using SYBR green supermix on a CFX96 real-time PCR detection system (Bio-Rad Laboratories) with gene-specific primers listed in Table S1. Relative expression level was determined. **MO and mRNA injection.** MOs were ordered from Gene Tools and injected into 1- to 2-cell stage embryos. A2b translation blocking MO (5’-CAA-TGGCGATGTGAGGGAACTCAG-3’, 5 ng) was injected at 1- to 2-cell stage. A2b splice-blocking MO (5’-AAAGGGAAGACCCCCTCAGG-3’, 2 ng) was designed against the splice donor site of exon 3. MOs were acquired every 5 min over 16 h (between 32 hpf to 48 hpf) in 17 planes using a Yokogawa spinning disk confocal and Nikon inverted Ti microscope. The objective was a Nikon 20× air Plan-Apo differential interference contrast NA 0.75. Images were acquired with dual Andor iXon s3 EMCCD cameras (512 × 512 pixels) and NIS-elements software. Confocal z-stacks were acquired every 5 min over 16 h (between 32 hpf to 48 hpf) in 17 planes spaced by 2 µm. Multiple stage-matched embryos were imaged in parallel using a moving XY stage. **Heat shock of Tg(hsp70:runx1).** The embryos of hsp70:runx1, either uninjected or injected with A2b MO, were heat-shocked twice at 38.5°C for 30 min at 3-somite stage and at 22 hpf. Embryos were then fixed at 36 hpf for analysis. **Cell culture.** Primary HAEcs were cultured in EBDM-2 medium–supplemented EGM-2 medium containing hEGF, hydrocortisone, hFGF-β, VEGF, IGF-1, acidic fumaric acid, Heparin, fetal bovine serum, and Gentamicin/Ampicillin-B [GA] (Lonza). The cells were plated on gelatin-coated plates and kept under a humidified atmosphere of air/CO2 (19:1) at 37°C. **Measurement of CXCL8 secretion.** After HAEcs were cultured to confluence, cells were serum starved overnight and suspended in serum-free medium containing 1 U/ml adenosine deaminase. Cells were treated with chemicals at the desired concentration and incubated for 6 h. At the end of incubation, the culture media were collected, and the cells were lysed for total protein concentration measurement (DC protein assay; Bio-Rad Laboratories). CXCL8 concentration was measured using an ELISA kit (BioLegend). **cAMP luminescence assay.** After cultured to confluence, HAEcs were serum starved overnight. The cells were resuspended in fresh serum-free medium containing 1 U/ml adenosine deaminase and incubated at 37°C for 10 min. Before chemical treatment, cells were treated with 200 µM papaverine and incubated at 37°C for 10 min to block phosphodiesterase. Chemicals were added at the desired concentrations, and cells were incubated at 37°C for 15 min. At the end of incubation, cells were lysed for cAMP ELISA assay according to the manufacturer’s instructions (Enzo Life Sciences). A small portion of cell lysates was used to measure protein concentration. **Generation of cxcl8 mutant.** The cxcl8 mutant was generated with TALENs using backbones containing heterodimer endonuclease pCS27+ AL3RR and pCS2TAL3DD (Dahlem et al., 2011) and the Golden Gate TALEN kit (Cermak et al., 2011). The two TALEN arms are designed to target Danio rerio cxcl8 (NCBI Gene ID: 100002946) at 5’-TGGAG-GTCTGGCTGTAGAT-3’ and 5’-TGAACAGAAAAAGGCGCAAGG-3’. The cxcl8 mutant fish were identified by high-resolution melt analysis (Roche 049096310G). Primers were used forward, 5’-GAATGACCCTT-GAGAGGCTGGTCTG-3’; and reverse, 5’-GGAGGGAAGACCTCACA-CCTTTTAT-3’. To sequence individual F0 fish, genomic DNA was isolated from a fin clip using 50 mM NaOH. A PCR was run using the above HRMA primers, and the product was cloned into pCR4-TOPO (Life Technologies) and then transformed into DH5α competent cells. Six to eight colonies were grown up and sequenced using the M13R primer (5’-CAGGAAACAGCAGTATAGC-3’) to identify any mutations or deletions in the fish. The F2 heterozygous and homozygous mutant embryos were genotyped using the following primer pair: forward, 5’-GAACATGCA-AAAACATATAGC-3’; and reverse, 5’-AGGGGTCACAGACATCGT-TCC-3’. The PCR product was then sequenced to confirm the deletion of TCCGT at positions 214 to 219. **Online supplemental material.** Table S1 provides the primers sequences used in this study. Videos 1 and 2 are the time-lapse imaging of a control wild-type zebrafish embryo and an embryo in which A2b expression was knocked down; the two videos demonstrate that in A2b-deficient embryos, fewer...
